3. There are no characteristic signs of death by morphine. The only lesions are those that may usually be observed after death from asphyxia. The blood is dark and fluid; the brain, meninges, and lungs may be congested; the bladder is usually full of urine.

4. A wound inflicted during life is generally characterized by hemorrhage, coagulation of the blood, eversion of the edges, and retraction of its sides. It may also be inferred that the wound was inflicted during life if any of the following are noticed: The presence of inflammation, swelling, pus, or gangrene on the edges of the wound, or if there is any sign of beginning cicatrization.

5. *Rape* is carnal knowledge of a female by a man, unlawfully, forcibly, and without her free consent.

The *medical evidence* is based on: (1) Marks of violence about the woman's genital organs; (2) wounds, bruises, or other marks of injury on the woman or on the accused; (3) blood stains and seminal stains on the person or clothing of either party; and (4) the presence of any venereal disease on either party.

6. Rigor mortis is supposed to be due to the coagulation of the myosin in the muscles. It lasts for a variable period, generally from about sixteen to twenty-four hours.

7. *To identify blood stains:* (1) Some of the material from the suspected stain is thoroughly mixed with a few drops of a saturated solution of sodium chloride, and then allowed to evaporate to dryness on a slide covered with a cover-glass. Now add a drop of glacial acetic acid to the slide, and allow it to enter under the cover slip; then apply gentle warmth. If the suspected stain is *blood,* crystals of hemin will form later, and can be seen under the microscope; this will not be the case with *iron rust.*

Other tests are: (2) The demonstration of the *corpuscles* by the aid of the *microscope;* (3) *spectroscopic* appearance of two dark absorption bands in the green rays, and at the junction of the green and yellow rays; (4) *chemical* tests, and as the action of guaiacum and ozonic ether, nitric acid, or caustic potash.

8. *Strangulation* generally points to homicide; *hanging,* to suicide.

9. *Infanticide* is the murder of a newborn child, which has a separate existence from its mother.

In order to establish *infanticide,* it is necessary to prove: (1) That the child was born alive; (2) that it was capable of an independent existence; (3) that its death was due to violence; and (4) that this violence was criminal.

SURGERY.

3.

CONCUSSION OF THE BRAIN.	COMPRESSION OF THE BRAIN
Unconsciousness is incomplete; patient can be made to answer, though it may be briefly, and in simple words.	Complete unconsciousness; may scream into patient's ear at the top of the voice, but will receive no answer.
Special senses, though greatly blunted, are not abolished.	Special senses entirely suspended.
Power of movement not destroyed; if the position of a limb be changed the patient will resist or bring it immediately into the original position.	Complete or partial paralysis; in most cases hemiplegia.
Respiration is quiet and feeble.	Respiration full and noisy.
Pulse feeble, frequent, and intermittent.	Pulse full and slow, and sometimes laboring.
The stomach sickens and rejects its contents.	The stomach is insensible to any impression; no nausea or vomiting.
The feces may be discharged incontinently, as may also the urine, though not usually.	Bowels are torpid, and the bladder incapable of emptying itself, though the urine may escape by overflow.
Deglutition little impaired.	Deglutition difficult or impossible.
Pupils variable, though generally contracted; the eyelids somewhat open.	Pupils variable, though generally much dilated, and the eyelids closed.
Temperature of the body less than natural.	Temperature almost natural, a little below the normal standard.

—(From Treves' *Manual of Surgery.*)

5. In posterior luxation of the hip joint the patient should be placed on a mattress on the floor, and then be anesthetized. The leg is then to be flexed on the thigh, and the thigh flexed on the abdomen; adduction is to be increased so that the knee is beyond the middle line of the body; then abduct, freely circumduct outward, and finally extend the limb so that it is parallel with the other.

TOXICOLOGY.

1. The man took sulphuric acid.

2. *Post-mortem appearances caused by nitric acid:* "The lips, mouth, fauces, and esophagus will be stained a yellow or yellowish brown; the mucous membrane in the same regions will be softened, peel off readily, and probably be found in shreds. The stomach will probably be distended by gas, and, as is the case with any of the stronger acids, its walls may be softened, ulcerated, or perforated. The contents of the stomach will be green or yellow, the lining membrane congested. Similar conditions but diminished in intensity will be found in the upper part of the small intestine."—(Dwight's *Toxicology.*)

3. *Reinsch's test for arsenic* is as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean, dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

4. White of egg in moderation, followed by an emetic.

5. *The symptoms of chronic lead poisoning are:* Progressive emaciation, anemia, wrist drop, severe colic around the umbilicus, constipation, feces clay colored, blue line on the gums at the junction with the teeth, fetid breath.

6. A white precipitate is found on the addition of potassium ferrocyanide, ammonium sulphide, or barium chloride to an aqueous solution of zinc sulphate.

7. Alkaline carbonates, followed by an emetic.

8. *Treatment for poisoning by oxalic acid:* Promptly give magnesia usta or slaked lime in water or mucilage, followed, if necessary, by an emetic (unless corrosion is marked).

9. The man took croton oil.

10. *The symptoms of poisoning by opium or morphine* are as follows: At first there is usually a period of excitation, marked by restlessness, great physical activity, loquacity, and hallucinations. The patient then becomes weary, dull, and drowsy; he yields to the desire for sleep, from which at first he may be roused. The lips are livid, the face pale, the pupils contracted, and the surface bathed in perspiration. The condition of somnolence rapidly passes into narcosis. The patient cannot be roused, and lies motionless and senseless, with completely relaxed muscles. The pulse, at first full and strong, becomes feeble, slow, irregular, and easily compressible; the respiration slow, shallow, stertorous, and accompanied by mucous râles. The patient rapidly becomes comatose, and, in fatal cases, dies in from 45 minutes to 56 hours, usually in from 12 to 18 hours. In cases of recovery after the stage of narcosis, the pulse and respiration gradually return to the normal, and the condition of coma passes into one of deep sleep, lasting 24 to 36 hours.

Treatment: Wash out the stomach with a dilute solution of potassium permanganate, leaving about 500 c.c. in the stomach, and maintain the respiration. In the first or second stage the "ambulatory treatment" should be adopted to prevent, if possible, the establishment of the third stage. If this stage develop, the main reliance is to be placed in maintaining the respiration by artificial methods, until the poison has been eliminated. Strong coffee, or caffein, by the mouth or rectum, are of benefit. The same cannot be said of atropin. The urine should be drawn by the catheter.

PHYSICAL DIAGNOSIS.

1. (1) A systolic murmur, soft and blowing, heard best at the apex, and transmitted to the left axilla and toward the angle of the left scapula, indicates mitral regurgitation. (2) A presystolic murmur, harsh and rough, heard best very near the apex, and not transmitted, denotes mitral stenosis. (3) A diastolic murmur, soft, heard best in the second right intercostal space, and transmitted down the sternum or toward the apex, denotes aortic regurgitation. (4) A systolic murmur, harsh, heard best in the second right intercostal space, and transmitted into the carotids, denotes aortic stenosis. (5) A systolic murmur, heard best over the lower end of the sternum, denotes tricuspid regurgitation. (6) A presystolic murmur, heard best over the ensiform cartilage, and not transmitted, denotes tricuspid stenosis. (7) A diastolic murmur, heard best in the second left intercostal space, denotes pulmonary regurgitation. (8) A systolic murmur, heard best in the second left intercostal space, and not transmitted to the large vessels of the neck, denotes pulmonary stenosis. (9) A murmur, usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a hemic or functional murmur, and denotes as a rule an impoverished condition of the blood.

4. Pleuritic friction sounds may be distinguished from râles in the bronchial tubes, by being more superficial and localized, being heard during both inspiration and expiration, and not being modified by cough or deep inspiration.

6. In *bronchiectasis* the sputum is fetid and does not contain the tubercle bacillus; there is usually no fever, no loss of strength and no history of tuberculosis. The reverse conditions obtain in *pulmonary tuberculosis with cavity.*

7. If air be in the abdominal cavity there will be a tympanitic note on percussing the anterior abdominal wall (with patient lying on his back), and there will be no fluctuation.

8. *Bronchial breathing* may indicate consolidation of the lung, or a large cavity communicating with a bronchus; it is heard in phthisis, lobar pneumonia, and hemorrhagic infarction; it is also heard normally over the trachea and large bronchi.

9. *Pleuritic friction* sounds are synchronous with the respirations, and cease if the patient hold his breath. These conditions do not obtain in *pericardial friction* sounds.

PHYSIOLOGY.

1. *Physiology* is that branch of science which treats of the functions of living tissues and organs in a state of health.

2. The arterial circulation is caused by: (1) The elasticity and tone of the arteries, (2) the force and frequency of the cardiac contractions, (3) the resistance in the capillaries.

3. *The different stages of digestion* are: (1) *In the mouth*, where the food is crushed, mixed with saliva, and reduced to a pulp; a certain amount of starch converted into maltose and rendered slightly alkaline. Fats and

proteids are unaltered. (2) *In the stomach*, where the contents are rendered acid, conversion of starch into sugar ceases, connective tissue of fats is dissolved, and fats are set free. Proteids are dissolved and peptones formed. The albuminous foods are dissolved for the most part, and a grumous mixture of peptones, liquid fats, and starches is formed, which is termed chyme, and is gradually passed through the pylorus into the intestine. (3) *In the intestine*, where the chyme mixes with the bile, pancreatic and intestinal juices, becomes alkaline, conversion of starch into sugar recommences, emulsifying of fat begins, and the undissolved proteids are converted into peptones. The diffusible peptones and salts enter the portal vein, the fat in a fine state of division entering the lacteals. In the large intestine the liquid chyme becomes more and more solid, is rendered acid by fermentative changes, and acquires the odor of feces. (From Ashby's *Notes on Physiology.*)

The different fluids essential to the same are: Saliva, gastric juice, pancreatic juice, succus entericus, and bile.

4. The contents of the stomach at the close of gastric digestion are: Water, inorganic salts, acidified proteids, peptones, liquid fats, starch, cellulose and the indigestible residues of various foods.

5. *The coats of veins* are: (1) *Tunica intima*, endothelial cells on a basement membrane; (2) *tunica media*, muscle fibers and elastic fibers; (3) *tunica adventitia*, connective tissue of white fibrous and yellow elastic kinds.

The forces that cause the circulation in the veins are: (1) The action of the heart, (2) aspiration of the thorax, (3) the contraction of the muscles, and (4) slightly, the valves in the veins.

7. Serum differs from liquor sanguinis in that it (serum) contains thrombin and cell-globulin, and has lost fibrinogen and fibrin and a little calcium salt.

10. *The functions of the kidneys* are: (1) To separate the urine from the blood, (2) to excrete urea, and (3) the production of an internal secretion.

A NEW METHOD OF RECOGNIZING ULCERS OF THE UPPER DIGESTIVE TRACT AND OF LOCALIZING THEM.

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF INTERNAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

THE diagnosis of ulcer of the stomach is usually connected with a good deal of difficulty. Even in the presence of larger quantities of blood in the vomited matter or in the stool no positive diagnosis of ulcer of the stomach can be made. For on the one hand we may have a parenchymatous hemorrhage in the stomach without the presence of an ulcer; on the other hand we have enough cases of ulcer of the digestive tract, which run their course without any manifest hemorrhage or even without any occult blood either in the stomach contents or in the stool. If an ulcer is present its localization, whether in the cardia, pylorus, or duodenum, is rather difficult, at times impossible.

The gastroscope, which might be of aid, is at present not available in these cases, firstly on account of the difficulty of introducing the instrument; secondly on account of the danger of perforation. A method, which would make it possible to determine accurately the presence of an ulcer, and at times to localize it, would therefore be of considerable value. I have for a long time been experimenting with some such method and would like to communicate the results.

The method consists in the following: The patient swallows the duodenal bucket in a gelatine capsule about 9 P. M. The thread which is of braided silk (English, No. 5) is attached to the shirt in such a manner that it can pass in through the digestive tract for a distance of 75 cm. from the lips. The bucket is left in the digestive apparatus over night and is removed about 7 or 8 A. M., in the fasting condition. At the pylorus we often experience a slight resistance which is usually easily overcome; a greater resistance is offered at the larynx at the entrance of the esophagus. Here the patient must swallow and while the larynx moves upward the bucket may easily be drawn out. The thread is then closely inspected. In favorable cases of ulcer, particularly if the thread has come into intimate contact with the surface of the ulcer, we find a brown or dirty black discoloration of the thread at this point. The distance of this brown spot from the lips points to the seat of the ulcer. A blood stain in the neighborhood of 40 cm. points to an ulcer at the cardia, at 44 to 54 cm. ulcer of the lesser curvature, 56 to 58 cm. pylorus, 59 and more ulcer in the duodenum.

The method might be called the "thread impregnation test." Ulcers situated in the esophagus, cardia, lesser curvature, pylorus, and duodenum can best be recognized by this method, whereas

TABLE OF CASES OF ULCER OF THE UPPER DIGESTIVE TRACT, EXAMINED BY MEANS OF THE THREAD IMPREGNATION TEST

No.	Name	Hematemesis or Melena, Whether Present and How Long Ago	Brown Discoloration of Thread, Whether Present and at What Distance from Lips	Thread Test, How Often Made and Its Result	Remarks
1	G. McA.	Melena 4 years, 2 years and 1 month ago	+ 36–43 cm.	1 +	
2	Fr. Th.	Slight hematemesis a week ago	+ 33 cm.	2; 1 = +, 1 = 0	
3	Dr. R. M.	Hematemesis 6 months ago	+ 47–5 cm.	2; both +	
4	R. J.	Melena 2 years, 1 year and 3 weeks ago	+ 48–55 cm.	8, all +	
5	J. R. M.	Hematemesis 14 days ago	+ 46–51 cm.	1 +	Patient was operated and an ulcer was found at the lesser curvature (about the middle)
6	C. M.	Hematemesis about 4 weeks ago	0	2 both 0	
7	Dr. B.	Slight hematemesis a week ago	0	1 = 0	
8	R.	Hematemesis 3 weeks ago	+ 57½–59 cm.	2 both +	
9	B. F. B.	Hematemesis 3 years ago	+ 44–74 cm.	2 both +	At time of test the stomach was filled with blood and ischochymia was present.
10	W. H. v. G.	No previous history of hemorrhage	+ 53–54 cm.	2 both +	Occult blood was found neither in the stomach contents nor in the feces.
11	Dr. L.	Vomited blood 1½ years ago	+ 59–62 cm.	1 +	
12	J. F. H.		+ 61 cm.	2 both +	
13	M. O. S.		+ 61–66 cm.	1 +	Occult blood neither in stomach contents nor in feces.
14	N. B.	Vomited blood 4 weeks ago	+ 61–62 cm.	2; 1 + , 1 = 0	

ulcers of the fundus and the greater curvature cannot be discovered by this test. Ten cases without ulcer were tested with the thread test and a negative result obtained. In the following table I have grouped 14 cases of ulcer of the digestive tract in which the thread test with the duodenal bucket has been applied.

In eleven cases with hematemesis or melena the test was found positive in nine, whereas, in two it was negative. In three cases which were not preceded by hemorrhage the test was positive. Of these three patients two were operated upon and the diagnosis was confirmed. As both cases are of interest, I will give a short account of each.

Case I.—January 10, 1909. W. H. v. G., 45 years old, has been suffering for eight years from stomach pains, occurring about two or three hours after meals. This complaint occurs periodically, lasts two or three months, and alternates with varying periods of euphoria. Constipation occurs constantly; vomiting, however, has never been present. In the last three years patient has lost nearly 50 pounds. For the last three years patient has been washing out his stomach, and reports that he often finds food remnants in the fasting condition; sometimes, however, the stomach is empty. If the pains are intense, patient washes out his stomach and then generally feels much easier. As he has lately lost considerable flesh, and as his trouble became a great deal worse, he consulted me.

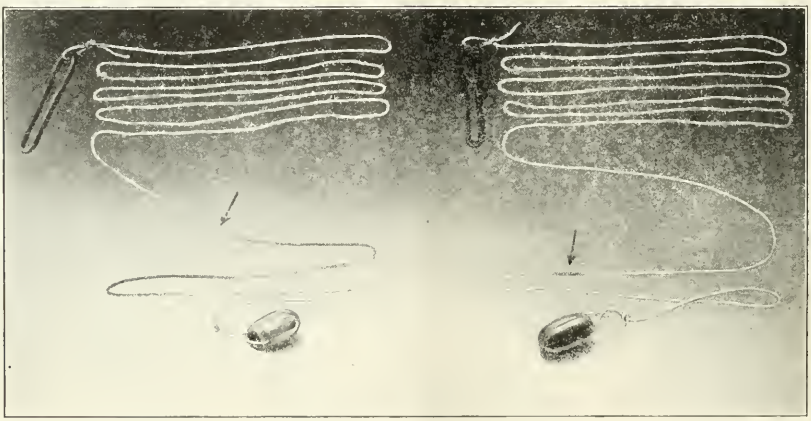
Status præsens.—The thoracic organs are normal. On examining the abdomen a marked dilatation of the stomach can readily be detected by means of clapotage. The stomach extends from the left ribs up to one to two fingers' width above the symphysis. Palpation does not reveal any particularly painful points in the abdomen; visible peristaltic waves, however, are elicited by palpation. They travel from left to right, and are recognized as originating from the stomach (peristaltic restlessness of the stomach). Examination one hour after a test breakfast shows: Free HCl, 60; total acidity, 80; no occult blood.

In the fasting condition the stomach, after a preceding meal of rice the night before, contained 100 c.c. of juice without food; HCl + acidity = 76. Patient was placed upon liquid diet and was given calcined magnesia and subnitrate of bismuth.

On January 12 the patient swallowed the duodenal bucket in a gelatin capsule; the following day in the fasting condition the bucket was removed. The bucket contained a light yellowish liquid of acid reaction but showing an absence of free HCl. The thread was colored yellow near the bucket. A little higher up a reddish brown spot 2 cm. in length was found, at a distance from 53 or 54 cm. from the teeth. (Table, Case X.) A few days later the test was repeated with the same result.

The diagnosis of ulcer of the stomach at the lesser curvature near the pylorus was made. Since the pylorus was still pervious, as shown by the rice test, and particularly the duodenal bucket, the peristaltic restlessness of the stomach and the marked dilatation as well as the occasional ischochymia pointed to a spastic contraction of the pylorus caused by the ulcer.

In spite of careful treatment the condition of the patient did not improve, and for this reason Dr. Willy Meyer did a posterior gastroenterostomy. During the operation the ulcer was found at the lesser curvature, and no thickening or narrowing of the pylorus could be discovered.



a *b*

Fig. 1.—Duodenal Bucket with thread, after a night's stay in the digestive tract of patient R. J. (Table, case 4); *a*, after ordinary foods; *b*, after a week's treatment with a strictly liquid diet. The arrow marks the place where the blood stain begins.

Case II.—December 20, 1908. J. F. H., 52 years old, has been suffering for eight years from severe pains, occurring about four hours after meals, and from frequent vomiting. These attacks usually lasted one to two months, interchanging with periods of euphoria lasting about six months. Up till February, 1905, the patient had lost twenty-five pounds, then he underwent a strict cure for ulcer (milk diet and rest abed) and then felt well for two years. Since 1907 the attacks recurred and patient again lost considerably in weight. The attacks of pain were now so severe that large doses of morphine had hardly any effect. There had never been any vomiting of blood.

President condition: liver somewhat enlarged; the right lobe of the liver is sensitive to pressure. Stomach slightly dilated, and off and on slight peristaltic restlessness of this organ may be observed. After a test meal a slight degree of hyperacidity (acidity = 75) is found.

In the fasting condition, after a previous meal of rice the night before, the presence of about 60 c.c. of gastric juice mixed with bile is found, but no food remnants.

The duodenal bucket test showed: Contents yellow; of alkaline reaction, fat-splitting ferment present. Thread discolored yellow at the bucket, higher up it is discolored brownish to the length of 1 cm. at the distance of 61 or 62 cm. from the teeth (Table, Case 12). We concluded from this test that the pylorus is permeable and that a small ulcer is situated in the duodenum not far from the pylorus, giving rise to an occasional spastic contraction of the pylorus.

Whereas at first I thought that in this case we had to deal, aside from the hyperchlorhydria, with gallstones, after recognizing the ulcer in the duodenum I discarded the other diagnosis. As the patient did not improve under suitable medical treatment, a gastroenterostomy was performed on him also by Dr. Willy Meyer. At the operation the gallbladder was found empty, the pylorus patent, and an ulcer with infiltrated margins was discovered one inch from the pylorus in the duodenum. Both patients are now doing well.

chymia and movable tumor of the pylorus, the introduction of the duodenal bucket produced real duodenal contents (slightly alkaline reaction, yellow discoloration due to bile, and presence of fat-splitting ferment). The thread showed no trace of brownish color and was only of a yellow bile-stained appearance at the lower 12 cm. of its length. I concluded that in spite of the tumor the pylorus was still perfectly passable for the duodenal bucket and that its surface was not ulcerated. A few days later the patient was operated upon by Dr. Willy Meyer in the German Hospital; a resection of the tumor was done. The pylorus was indeed entirely patent and its mucous membrane smooth and not ulcerated; at the upper part of the pylorus two carcinomatous nodules were attached, but were still covered with mucous mebrane. Here we could determine the mechanical conditions of the pylorus before the operation.

In as far as it appears to be advantageous to recognize ulcers also in regions that are not accessible to the thread I attempted to make use of the same principle of impregnation in these instances, too.

The method consists in the introduction into the

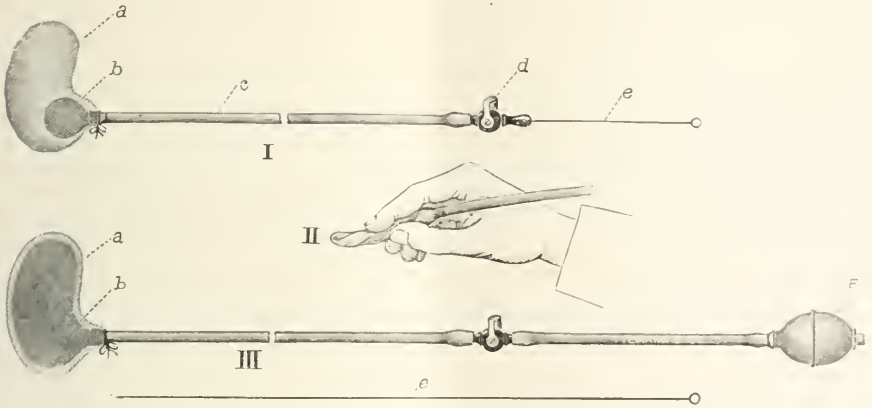


Fig. 2.—The Gastric Stamper: *a*, silk gauze bag; *b*, rubber balloon; *c*, tube; *d*, cock; *e*, stilet; *f* bulb. I. Gastric Stamper, with collapsed balloon. II. The gauze bag and balloon folded up around the tube, ready for introduction. III. Balloon filled with air, following the outline of the gauze bag.

This test seems also to be of value in judging objectively as to the result of treatment of the ulcer. Thus we noticed in patient R. J. (Case 4) that after liquid diet the test was less marked than after coarser food. The illustrations (Fig. 1) show test *a*, after a moderately solid diet, and test *b*, after a strictly liquid diet. The good influence of strict diet can readily be recognized. As soon as we put patient on a more solid diet we obtained tests that looked like *a*.

The thread impregnation test cannot, of course, indicate whether we have to deal with a benign or a malignant process. The usual clinical symptoms have to be considered, which in most cases easily enable one to make the diagnosis. The position of a neoplasm, especially if its surface is somewhat ulcerated, can also often be ascertained by the thread test.

If we can be sure that the bucket was in the duodenum, we can exclude the presence of active ulceration at the pylorus or the duodenum if the lower part of the thread is not discolored either brown or black. In a patient (J. K.) with ischo-

stomach of a rubber bag, surrounded with silk gauze which is inflated and left for a half hour in this condition. The walls of the stomach are thus in close contact with the inflated bag. Finally the air is allowed to escape and the collapsed balloon is withdrawn. If an ulcerated surface is present in the stomach we get a blood spot on the gauze at the corresponding point.

I have used this method several times and have occasionally obtained positive signs of ulceration. The instrument used for this purpose consists of a rubber tube with mandrin and stopcock, a rubber balloon, and a silk gauze bag surrounding the latter (see Fig. 2). The gauze bag is shaped like the stomach, the balloon also assuming this form after inflation. The instrument could probably best be called the "gastric stamper."

The procedure is as follows: The patient must have an empty stomach, otherwise the organ has to be washed out. The gastric stamper, provided with the mandrin, is placed in lukewarm water. The balloon is entirely emptied of air and is laid around the lower end of the tube with the gauze

bag around it (see Fig. 2, II.). Grasping this lower part like a pen, but with a little more pressure, it is pushed, after depressing the tongue of the patient with the left index, into the throat and down into the stomach. The mandrin is withdrawn and the patient lies down; now we inflate the balloon just sufficiently to fill the gauze bag and the stopcock is closed. The patient remains quiet for a half hour; then the air from the balloon is allowed to escape and the stomach stamper is withdrawn in the sitting posture; again the balloon is blown up and is hung up to dry for a few hours.

The dried bag thus shows an impression of the stomach and we can recognize from any visible blood spots—if there are any—where the ulceration is. Mucus can also be recognized after drying and we can see in which region of the stomach it collects.

The gauze bag can readily be removed from the balloon and may be preserved. Of course it is used but once and for every examination a new gauze bag is requisite.

The duodenal bucket as well as the gastric stamper must of course first be sterilized before each application.

Finally I desire to state that the thread impregnation method by means of the duodenal bucket* can be used without any difficulty in all patients suspected of ulceration. In each case a new silk thread must be used. We can in this manner often arrive at a positive diagnosis of ulcer and its situation. Sometimes the size of the ulcer can also be approximately reckoned by the length of the stain; occasionally there are two brownish dots on the thread at a distance of about one centimeter apart; these probably mark the margins of the ulcer.

The introduction of the gastric stamper is somewhat more difficult and can be done only in patients who are used to lavage, and in whom the latter procedure is not contraindicated. This method must still be worked up a little more before it may become of general use. I shall be pleased to report upon it again at some future time.

POSTURAL LUNG-DULLNESS; ITS VALUE IN DIAGNOSIS AND TREATMENT.

By ALBERT ABRAMS, A.M., M.D.,

SAN FRANCISCO.

Pulmonary Resonance.—Over the lung, as over any other air-containing organ, percussion yields a clear sound which is called pulmonary resonance. The physiologist assumes that the lungs are in a stretched condition, yet the clinician finds that even in the norm certain portions of the lungs are collapsed and deprived of sufficient air to yield a dullness, and, in some instances, flatness on percussion. Thus, what the author has called "atelectatic zones"[1] may often be demonstrated even in healthy individuals. They are circumscribed areas of pulmonary atelectasis, dissociated with any demonstrable lesion, varying in size from a twenty-five cent piece to a dollar or larger, and disappearing after a deep inspiration or upon application of the lung reflex test. They usually reappear, however, after a few minutes when tranquil breathing is resumed. In the accompanying illustrations (Figs. 1 and 2) a composite picture is projected defining the usual situation of the zones based on an examination of over one hundred apparently healthy individuals (children as well as adults). These zones are frequently mistaken for areas of lung consolidation, either when detected by percussion or seen at an *x*-ray examination. The zones are frequently present in what

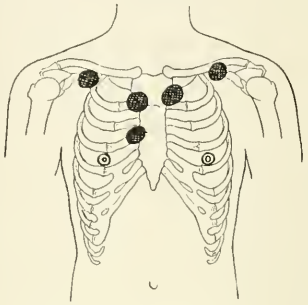

FIG. 1.—Atelectatic zones on the anterior surface of the chest.

the author has called "pulmonary anemia,"[2] and they also bear a definite relation to the points of election and paths of distribution of the lesions in chronic pulmonary tuberculosis. Very often in apparently healthy persons the lungs are hyperresonant on percussion, dependent on a pulmonary neurosis, which the author has called "acute lung dilatation."[3] The picture presented in this condition is essentially that of emphysema. By means of the cocaine test, *i. e.* cocainization of the nasal mucosa, the atelectatic zones will disappear and so will the condition of acute lung dilatation. The author has shown[4] clinically that the vagus contains constrictor and dilator fibers for the bronchioles, which observation was demonstrated later as correct by the physiological experiments of Dixon and Brodie.[5] The action of the dilator fibers can be inhibited reflexly by cocainizing the nasal mucosa, hence resonance on percussion will substitute hyperresonance, and similarly if, in consequence of a nasal anomaly the constrictor fibers are irritated, cocaine by inhibiting their action will translate dullness into resonance. Many clinicians employ a plexor and pleximeter in percussion, and by so doing they unknowingly elict

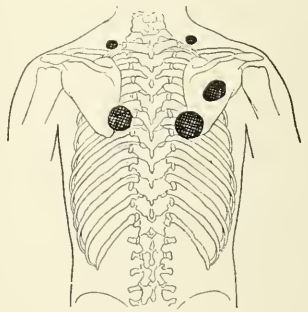

FIG. 2.—Atelectatic zones on the posterior surface of the chest.

the lung reflex of contraction,[6] which will yield a dullness on percussion.

Tissue Vulnerability.—Cutaneous and other complications can be anticipated in diabetes mellitus for the reason that the disease is demonstrated by the presence of sugar in the urine. In pulmonary tuber-

*The duodenal bucket, as well as the gastric stamper, are made by Tiemann & Co., New York.

culosis, however, this tissue susceptibility is ignored, hence the pulmonary condition preceding tuberculosis is unrecognized. The pretuberculous lung is essentially an emphysematous lung, and characterized by hyperresonance on percussion, extension of the lung borders, and the lung when percussed either at

Fig. 3.—The vibrosuppressor.

the height of forced inspiration or expiration shows no change in the percussion note. The restricted diaphragmatic movements peculiar to early phthisis owe their origin to the emphysematous lung condition.

Vibrosuppression.[7]—If one percusses the normal lung the sound elicited is the product of the vibration of the lung tissue and the thoracic walls. It is the summation of this vibration which interferes with the elicitation of the dullness of the airless organs in juxtaposition to the lungs. The sternum is practically a sounding board, and by the elimination of its vibrations localized areas of lung dullness can be demonstrated which otherwise would escape recognition. Thus, in early phthisis, resonance (owing to lung dilatation) is the usual phenomenon obtained by percussion, but if vibration of the sternum can be excluded dullness of one or both apices may be elicited. During percussion the vibrosuppressor may be used (Figs 3 and 4), or the lower end of the sternum may be forcibly compressed by the hand of the patient, or, better still, by an assistant. With these preliminary facts at our command, the reader will be able to appreciate better the observations of the author concerning postural lung dullness.

Postural Lung Dullness.—Percussional results are often influenced by the prejudiced preconceived ideas of the physician. The skilled clinician in his interpretation of percussional phenomena is guided not so much by the ear as by the *tactus eruditus;* thus, palpatory percussion will often yield results which would wholly escape the observer who is influenced only by what he hears and not by what he feels. Any one, however, reasonably skilled in percussion will, when attention is called to the fact, recognize a decided difference in the percussion note of the lungs if percussion is made first in the erect and then again in the recumbent posture. One will also note a difference if the patient is percussed first leaning far forward and then backward (supported by an assistant). In other words (the author is assuming an average typical normal subject), the percussion changes correspond in a minor degree to the alterations in the percussion note when fluid is present in a pleural space. The changes noted would be as follows:

Leaning far forward: Anterior chest region diffused dullness, especially marked in a definite area (Fig. 5). Posterior chest region hyperresonant.

Leaning far backward: Posterior chest region shows diffused dullness, notably in a definite area (Fig. 6). Anterior chest wall elicits a hyperresonant percussion note.

Leaning to one side: Side of chest wall toward which patient inclines shows dullness, whereas the other side is hyperresonant.

Lying on one side: Side of chest on which the patient lies demonstrates dullness of the lung, including the apex, whereas the other side is hyperresonant.

Recumbent posture: The anterior thoracic wall is decidedly more resonant than in any other posture.

Prone posture: The posterior thoracic region is more resonant than in any other posture.

Exaggerated Trendelenburg: Slight dullness of the pulmonary apices; lower chest region hyperresonant.

Differential Diagnosis: Postural dullness as a pathological phenomenon is frequently encountered and may be confounded with the dullness of atelectasis. Dullness dependent on atelectasis is usually circumscribed and may be dispelled by a series of forced inspirations, rubbing the skin over the area of dullness to provoke the lung reflex of dilatation and by the cocaine test already cited.

Fig. 4.—Method of application of the vibrosuppressor.

Postural dullness is usually diffused, involving one or more lobes, and cannot be dispelled by forced inspirations, the cocaine test, or by exciting the lung reflex. The dullness in question, however, disappears at once by a complete change in the posture of the patient. Assuming, for example, that the dull-

ness is somewhere over the posterior surface of the chest, its dissipation cannot be effected until the patient assumes the prone posture.

Etiology of Postural Dullness.—After a careful consideration of this subject the author is constrained to conclude for the following reasons that

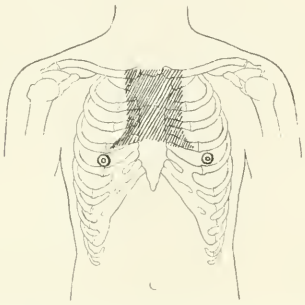

FIG. 5.—Dullness on the anterior surface of the chest when the patient leans far forward. The point of maximum intensity of the dullness is at the sternal insertion of the second ribs.

the dullness provoked by posture is dependent on the blood normally present in the blood-vessels of the lungs, which is influenced by gravity, like any other fluid:

1. The blood in the lungs, unlike in other viscera, is not restricted in amount, owing to the absence of vasomotor nerves. 2. The area of most pronounced dullness (as influenced by posture)) corresponds to the situation of the largest pulmonary vessels, and is least manifested in areas where the vessels are less abundant. 3. In passive congestion of the lungs observed in cardiopaths, the dullness elicited by postural changes is most pronounced. 4. The postural dullness is uninfluenced by all the maneuvers which act upon either the bronchoconstrictor or bronchodilator nerves of the vagus.

Postural Lung Dullness in Disease.—As already observed, postural lung dullness is observed as a normal condition, or perhaps, to speak more definitely, in the norm lung resonance is modified by posture. In passive congestion of the lungs it is most pronounced. In pulmonary tuberculosis I have noted only slight impairment of lung resonance as

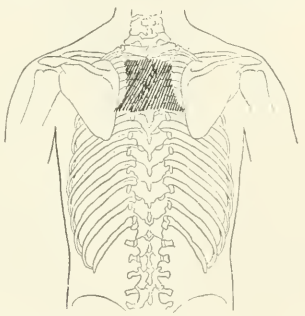

FIG. 6.—Area of dullness when the patient leans far backward.

determined by posture, and this observation applies with equal cogency to the pretuberculous lung. For this reason I seek to augment the quantity of blood in the apices of the lungs by having my tuberculous patients raise the foot of the bed so that the blood will gravitate toward the apices. After this manner I endeavor to induce a passive hyperemia of the regions in question. I cannot speak of results, inasmuch as this innovation has not been subjected to the test of time. Sir James Barr,[8] in his erudite Bradshawe lecture before the Royal College of Physicians, London, refers to the frequency of atelectasis in exhausting diseases, which may be mistaken for a pleural effusion. He furthermore says: "Atelectasis is often mistaken for hypostatic congestion of the lung, and forcible rubbing of the affected side, acting through the lung reflex of Albert Abrams, causes some expansion of the lung and clears up the percussion note." My observations do not tally with the latter. On the contrary, ever since I recognized the method of differentiating lung atelectasis and lung hyperemia, I am convinced that what is frequently regarded as atelectasis is in reality a passive congestion.

Grocco's Sign.[9]—The paravertebral triangle of dullness observed when there is a collection of fluid in one pleural sac is by no means characteristic of a pleural effusion, inasmuch as it has been noted in lobar pneumonia, pregnancy, and other extrathoracic affections. I have observed this sign very frequently in the norm, either on one or the other side when the patient assumed the lateral posture. The triangle of

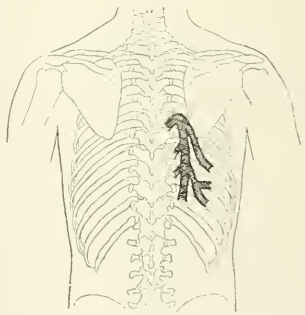

FIG. 7.—Arrangement of the pulmonary blood-vessels corresponding to the paravertebral triangle of dullness.

dullness is accentuated if, during percussion, the vibration of the vertebral column is suppressed by pressure with the hand, the spine, like the sternum, acting as a sounding board. When Grocco's sign is obtained in the norm it cannot be dissipated by the lung reflex of dilatation, but disappears at once when the patient assumes the prone posture. For the latter reason I assume that the sign in question is dependent on passive lung hyperemia. If one views a picture of the arrangement of the pulmonary vessels (Fig. 7), one notes that in the event of passive hyperemia any dullness ensuing would be triangular in shape. If Grocco's sign is present in a pleural effusion, or lobar pneumonia, it is for the reason that in either condition the vibrations of the spine are suppressed by the fluid or consolidated lung. Again in pleurisy, there is practically always a passive hyperemia of the lungs, inasmuch as there is a coexisting cardiac enfeeblement superinduced by a pleural reflex. The writer has frequently directed attention in the literature[10] to various methods for inhibiting the heart action (heart reflex of Abrams), but he has only recently noted that, if firm pressure is made with the finger in any of the intercostal spaces, the heart reflex ensues, which is manifested by a feeble or even inhibited pulse. He believes that

syncope and even death following thoracentesis is dependent on this fact.

Postural Dullness in Treatment.—The empirical treatment of pulmonary affections by external applications to the thoracic wall is fully justified, since the lung reflex of dilatation has been recognized. The postural treatment of diseases of the lungs is equally justified by the foregoing observations of the author. One fact, however, must be emphasized, and that is, the posture assumed by the patient must be an extreme one. Thus, to contend against hypostatic congestion the patient must assume the prone posture at least for a time several times a day. In hemoptysis, the correct posture can be determined when the area involved in the bleeding yields a resonant percussion note and indicates the exsanguination of the area in question. Amyl nitrite inhalations, as the author has shown,[11] are of decided value in hemoptysis, and owe their efficiency to exsanguination of the lungs by provoking the lung reflex of contraction. So it is with a variety of cardiorespiratory diseases, which need not be described in detail. The fact is that the author has not studied the phenomenon of postural dullness over a sufficient length of time to warrant his formulating conclusions in morbid conditions, and this contribution must only be regarded in the nature of a preliminary report.

246 POWELL STREET.

ANAPHYLAXIS AND IMMUNITY.*

BY EUGENE F. McCAMPBELL,

COLUMBUS, OHIO

ASSOCIATE PROFESSORR OF BACTERIOLOGY, OHIO STATE UNIVERSITY, CONSULTING PATHOLOGIST, COLUMBUS STATE HOSPITAL.

THE injection or transfusion of the blood of one species of animal into another of different species very frequently causes toxic symptoms and leads to fatal results. This fact has been known for many years, and long since the practice of blood transfusion from animal to man has been abandoned except in rare cases of anemia and poisoning.

It is not necessary at this time to consider the many examples of intoxications due to foreign bloods. I would call your attention, however, to one case; the action of the blood serum of the horse upon man in the treatment of diphtheria and tetanus by antitoxins. As is well known, the antitoxins for diphtheria and tetanus are made by actively immunizing the horse to the toxin of the diphtheria bacillus and tetanus bacillus, respectively, or to mixtures of the specific toxins and antitoxins which have been previously prepared. In the blood serum of the immunized horse there is developed the antitoxin, a definite substance about which little is known chemically. This horse serum after removal from the animal is standardized, a small amount of preservative added, and it is then bottled and placed on the market. We then inject horse serum containing antitoxin for diphtheria or tetanus, as the case may be. What is the effect of the injection of this foreign blood serum into man? After the majority of injections of antitoxin no pathological symptoms develop. However, in a certain percentage of cases, with which I dare say most of you are familiar, there is some fever, nausea, pain in the joints, urticaria, edema, and inflammations of the lymph nodes and kidneys. Occasionally death occurs following marked symptoms which we shall discuss later. I would call your attention to the fact that these reactions appear only after a period of eight to thirteen days subsequent to the injection of the antitoxin. Von Pirquet and Schick applied the name "serum disease" to reactions of this kind. The first observation of a skin eruption from foreign blood transfusion was made in 1874 by Dalera, an Italian. Quite recently several cases of death and some in which very serious symptoms have resulted have been reported in man. I would direct your attention to two cases of death among several following the injection of antidiphtheritic serum for both asthma and the prophylaxis and treatment of diphtheria in this country.

CASE I, reported by Dr. H. F. Gillette, Cuba, N. Y. (*Journal American Medical Association*, January 4, 1908).—Patient's age, 52 years. Rheumatic attack 15 years previous. Has asthma and bronchial catarrh. Patient was given 2,000 units of antidiphtheritic serum under the left scapula for asthma. He developed a prickling sensation within the chest and neck, had dyspnea and tonic spasms, and died in five minutes after injection of serum.

CASE II, reported by Dr. S. N. Wiley, Norristown, Pa. (*Journal American Medical Association*, January 11, 1908).—Patient's age, 34 years, and in the best of health. Patient was given a prophylactic injection of 1,000 units of diphtheria antitoxin. He soon developed an intense itching and burning sensation, dyspnea, edema and cyanosis of the face, paralysis, and convulsions. The patient died in five minutes after receiving the injection. The heart continued to beat for some time, death evidently being due to paralysis of respiration.

There are many other cases reported in the medical literature of this country where injection of antitoxin has given rise to serious intoxications. Von Pirquet and Schick, of Vienna, in their monograph on "Die Serumkrankheit" report several cases of untoward results from various antiserums from the horse, of which antidiphtheritic serum was the most common one used

It is obviously of great importance to determine whether these reactions are due to the antitoxin in the serum, to the horse serum, or to both. Positive proof is at hand, without going into details of this proof, showing that the antitoxin is not the toxic substance and is absolutely bland. Neither is there any toxin or toxon present to account for this reaction. It has been demonstrated that rabbits, guinea pigs, and other animals, in addition to man can withstand with no inconvenience very large injections of normal horse serum. However, if a guinea pig is given a small injection, say 0.004 (1/250) c.c., then a somewhat larger injection say 0.1 (1/10) c.c., after an interval of eight to thirteen days the guinea pig usually dies or is seriously in

*Read by invitation before the North Side Medical Research Society, Columbus, Ohio, January 14, 1909.

toxicated, showing very similar symptoms to those fatal cases in man, although often more pronounced. In animals, as in man, death is due to paralysis of respiration. I may say that in my own experience in guinea pigs I have observed the heart beat for two hours and forty minutes after respiration had ceased.

On carefully analyzing the above experiment, we find that as a result of the first injection of horse serum the animal has been rendered hypersensitive to some protein in the horse serum, so that symptoms of a serious intoxication develop after a second injection of a somewhat larger amount. We also find that, in order to render the animal susceptible to the protein of horse serum, an interval of at least eight to thirteen days must elapse before the second injection. If the second injection is given within this period the animal does not react, and usually on being injected subsequently at the proper interval it does not react; in other words, a state of immunity to the protein of horse serum exists. The state of hypersusceptibility probably lasts throughout life, judging from the experiments on animals.

It has been found that all proteins with the exception of gelatin will produce the reaction of hypersusceptibility the same as the proteins of horse serum.

To this condition of hypersusceptibility or supersensitiveness to proteins the name *anaphylaxis* has been given by Richet. Anaphylaxis, from the Greek (against protection) suggests also the antithesis of prophylaxis. In the above mentioned experiments when a rather large injection of horse serum is given within the so-called "period of incubation" a condition of *antianaphylaxis* results, which is nothing more than immunity.

Small injections usually hypersensitize, large injections produce immunity. Individuals may also be in a state of anaphylaxis or hypersusceptibility and antianaphylaxis or acquired immunity at the same time. To this condition Von Pirquet applies the name "allergie" to distinguish the condition from absolute immunity. As examples of the condition of "allergie" I might mention the acquired immunity of the syphilitic against syphilis, the leper against leprosy, the vaccinated against smallpox, etc. If the infection recurs, the reaction of the individual differs markedly from that observed in the primary infection, and the individual is to some degree immune.

In order that we may have some concrete and well known examples of the condition of anaphylaxis before we proceed further with this discussion, I would mention the mallein and tuberculin reactions for glanders and tuberculosis, respectively. As you all know, when these two toxic products in proper amounts are injected into healthy individuals no reaction occurs, but in those individuals having glanders or tuberculosis we have a state of hypersusceptibility or anaphylaxis, so that when the toxic products of the bacteria concerned in these diseases are injected we get a pronounced reaction. In other words, then the individual is hypersensitive or anaphylactic to mallein or tuberculin, as the case may be.

The question as to how or why certain individuals are anaphylactic to the horse serum of diphtheria and tetanus antitoxin, of course, occurs to us. This question we will have to leave open for the time being and subsequently take it up for discussion.

As stated above, it has been found that many if not all proteins except gelatin, which is very low in aromatic radicals, will give the anaphylaxis reaction. Egg-white, milk, various animal sera, certain vegetable proteins such as zein, gliadin, and various species of bacteria and yeasts have been used.

Those interested in the historical side of this question, I would refer to an article by Rosenau and Anderson, in the Bulletin of the Hygienic Laboratory of the Public Health and Marine Hospital Service, No. 29.

Let us now take up for a brief discussion the various substances and propositions concerned in this anaphylaxis reaction.

The Anaphylaxis Reaction.—Before going extensively into the mechanism of the reaction it might be well to review the symptoms which experimental animals such as guinea pigs show when sensitized and intoxicated by proteins. The severity of the reaction depends upon the protein used and the resistance of the animal. The animal, a guinea pig for example, having been sensitized by a minute dose of a protein, now receives, after an interval of eight to thirteen days, a second injection of the same protein. It makes practically no difference whether the injection is made intraperitoneally or subcutaneously. However, if the second injection is given intradurally or intravenously symptoms develop very rapidly and the guinea pig is usually dead in a few minutes. Usually in from five to fifteen minutes in the case of horse serum and egg-white and somewhat longer in the case of other proteins, the guinea pig shows an increase in respiration, giddiness, followed shortly by scratching and spasmodic coughing. Later, marked nervous symptoms, characterized by restlessness and tremors, develop. Subsequent to this the pig almost invariably becomes paralyzed in the hind extremities and the paresis gradually extends over the whole body. Convulsions and death usually follow. The period occupied in this reaction may be from ten minutes to several hours. Guinea pigs may be completely paralyzed and then recover. The prognosis is decidedly unfavorable when convulsions appear. Those guinea pigs in which symptoms develop slowly rarely died.

Furthermore, a guinea pig may be sensitized to several proteins at the same time. This point will be discussed later.

The question now arises as to the nature of the sensitizing substance and whether sensitization comes on rapidly or slowly. The question as to the nature of the intoxicating substance also presents itself.

The Sensitizing and Intoxicating Substances.—It has been suggested by Rosenau and Anderson that the chemical substance which sensitizes is perhaps of the same nature as that which subsequently poisons. Several investigators, among them Otto, Besredka and Steinhardt, Rosenau and Anderson, Gay and Adler, Gay and Southard, have devoted much time to the isolation of the chemical substance concerned in sensitization but without success.

This substance is not affected by phenol or any of the agents used in preserving sera, by formalin, or by drying. It is precipitated by ammonium and magnesium sulphate, but its chemical nature is not changed. The sensitizing proteins of blood serum are not affected by a temperature of 60° C. (140° F.) for thirty minutes, and do not dialyze through a collodion sac in the abdomen of a guinea pig.

The blood serum of a sensitized animal may be drawn and injected in somewhat larger amounts than in the first case into a second animal and thus render that animal hypersensitive or anaphylactic in a much shorter period. This experiment shows this sensitizing chemical substance or anaphylactin to be in the blood serum and to act similarly to the aggressins of bacteria.

It must be remembered that this sensitizing protein is not necessarily present in large amounts. It has been found that 1/1,000,000 c.c. of horse serum will sensitize more quickly than 10 cc. The best results have been obtained by using 1/100 to 1/1,000 c.c. of serum for sensitization.

Gay and Adler (*Journal of Medical Research*, 1908, p. 433) found that the (euglobulin) precipitate obtained by one-third saturation of horse serum with ammonium sulphate was sensitizing, but not intoxicating. This substance is identical with the anaphylactin of Gay and Southard. The successive fractions thrown down possessed less sensitizing and more toxic substances until complete saturation, when the preciptate was distinctly toxic and possessed very slight sensitizing properties. Gay and Adler have not been able to separate distinctly these elements from each other. These results seem to indicate that in horse serum the sensitizing and intoxicating substances are distinct and separate. The anaphylactin derived from one-third saturation with ammonium sulphate is, according to Gay and Adler (*Journal Medical Research*, 1908, p. 449), "(1) non-toxic for sensitized animals; (2) repeated large doses not only cause no refractory phase, but abbreviate the period of incubation; (3) its injection into sensitized animals not only does not intoxicate, but also produces no refractory or antianaphylactic stage; (4) it may give rise to sensitization of normal individuals in a few days (four or five), as does the transfer of blood from a sensitized animal."

Ether extracts and filtrates after precipitation with ammonium sulphate are neither sensitizing nor intoxicating. The substances concerned in this reaction are evidently proteins.

Attempts have been made to isolate the toxic or intoxicating agent in a pure state, but with no more success than has attended the isolation of the sensitizing substance. If this toxic principle could be eliminated, destroyed, or neutralized in horse serum, undoubtedly cases similar to those which have been referred to would not occur. Heating horse serum to 100° C. (212° F.) for twenty-five minutes destroys the toxic substances, but it would also destroy any antibodies which might be present. The intoxicating substance is not affected by freezing or by exposure to *x*-rays. Drying, dialysis, and filtration produce no effect. It is not altered by such chemical reagents as ammonium and magnesium sulphate, calcium chloride, silver nitrate, and formaldehyde or by ferments such as pancreatin, diastase, rennin, emulsin, myrosin, invertin, and acid and alkaline pepsin, or by such substances as inglutin, malt, papain, stropine, strychnine, morphine, and caffeine.

Rosenau and Anderson have found that the toxic effects of normal antitoxin and that refined by precipitation, when used in the same proportions, are equal for sensitized animals. They found the intraperitoneal minimum lethal dose to be one-tenth of a cubic centimeter (0.1 c.c.), the intracardiac minimum lethal dose one one-hundredth of a cubic centimeter (0.01 c.c.), and the intracranial minimum lethal dose one-twenty-fifth of a cubic centimeter (0.04 c.c.) for guinea pigs.

In support of the view that both the sensitizing and intoxicating substances are the same, Vaughan and Wheeler (*Journal of Infectious Diseases*, 1907, p. 476) claim to have obtained positive results with egg-white, which, by boiling with absolute alcohol and two per cent. sodium hydroxide, they have split into a toxic and non-toxic portion. They state that in their opinion, and they seem to have some evidence, the first or sensitizing dose of a protein causes a specific enzyme to be developed by the cells and that this enzyme at the second injection of egg-white splits out the poisonous radical which they have demonstrated, and intoxicates the animal. They have shown that this poisonous radical, when isolated and injected into animals, produces the same symptoms as the anaphylaxis reaction. I would call your attention also to the fact that Vaughan and Wheeler seem to have shown that the proteins of the bacterial cell, with the exception of the pneumococcus, may be split up and show the same properties in the same way as egg-white and horse serum. Furthermore, Wells (*Journal of Infectious Diseases*, 1908, p. 454), working with pure proteins, both animal and vegetable, has arrived at the same conclusion in regard to the sensitizing and intoxicating substances in the anaphylaxis reaction being the same. He has shown that one-twentieth of a millionth of a gram of pure egg-white (triple re-crystalized) will sensitize a guinea pig, and that one millionth of a gram will sensitize fatally, and he also finds that "the minimum lethal dose for sensitized guinea pigs is about one-half a milligram when injected intraperitoneally and one-tenth to one-twentieth of a milligram when injected into the circulation." Wells found that the minimum sensitizing and intoxicating doses of unpurified egg-white were respectively about one one-hundredth and one-fifth of that of the pure crystalline egg-white. The very small amounts of both pure and impure egg-white which will sensitize and intoxicate proves that it is the same molecule or two molecules of the same kind. It seems, therefore, that certainly in the case of egg-white and also in the bacterial proteins the same element sensitizes and intoxicates. In the case of horse serum we have no such positive proof, but in all probability the sensitizing substance is euglobulin or closely related to it and the intoxicating agent one of the higher proteins, perhaps an albumin.

The anaphylactic substance usually appears in the serum of the injected animal about the ninth or tenth day on the average. However, guinea pigs may be sensitized by intradural injections in seven days.

Certain important phases of the chemistry of the anaphylaxis reaction are interesting and important, but must be passed at this time. Only a few points additional along this line need to be mentioned. The aromatic radicals of the protein molecule are closely related to species specificity. When these radicals are combined with certain substances such as iodine they may be saturated. Proteins thus saturated are especially weak in their sensitizing and intoxicating power. This suggests, obviously, that these radicals are concerned in the reaction. Digestion with trypsin gradually destroys the sensitizing and intoxicating principles. I would refer those interested in the chemistry of anaphylaxis to an article by Wells in the *Journal of Infectious Diseases*, 1908, p. 449.

The question arises as to whether the anaphylaxis reaction is a specific reaction. It has been shown that guinea pigs sensitized to horse serum are extremely sensitive to horse serum and only slightly so to the sera of the dog, cat, rabbit, hog, sheep, chicken, or man. Conversely, guinea pigs sensitized to any of the foregoing sera are not very susceptible to horse serum, but react best with the specific sera. Guinea pigs sensitized to horse serum or any of the sera above mentioned will not react with proteins of a different nature such as milk or egg-white, and conversely. The reaction is for all practical purposes quite specific. An animal may, however, be in a state of anaphylaxis to several different proteins at the same time if it has received a previous sensitizing injection. I have observed animals anaphylactic to egg-white, milk, and horse serum at the same time.

Guinea pigs sensitized to human milk do not react to cow's milk, and conversely, showing the specificity in this instance. Guinea pigs sensitized to sheep's milk react to cow's milk. This shows that a close relationship of species of animals is not essential, but that the reaction is due to some chemical substance which is common to both. The crossing of various samples of white-of-egg from different animals shows also only a fair degree of specificity.

I now direct your attention to the fact that guinea pigs may be sensitized by feeding them either serum or meat. Rosenau and Anderson fed guinea pigs dried horse meat and successfully sensitized them to horse serum. Likewise, guinea pigs reacted to ox serum on being sensitized to beef. Cooking the meat entirely destroys its sensitizing powers. It has not yet been proven whether it is possible to cause an intoxication by feeding after a certain "period of incubation" subsequent to sensitization by feeding. If such be the case, it has been suggested that an explantion may be furnished for the idiosyncrasies of some individuals in regard to certain articles of diet such as eggs, fish and other sea foods, and perhaps strawberries, pineapples, etc., which always cause serious symptoms of intoxication. The process of sensitization to the proteins of these materials is as yet undetermined, but such must have occurred at some time previous.

Hereditary and Antenatal Transmission of Anaphylactic Substances.—Another interesting and important phase of the anaphylaxis reaction, namely, the question of hereditary and antenatal transmission, must be considered.

One of the first observations made was that the offspring of female guinea pigs sensitized to horse serum were themselves sensitive to horse serum. I have several times confirmed this observation and also noted the same conditions with some other proteins. In the transmission the male is not concerned, the function being entirely maternal. Anaphylaxis is not transmitted beyond the first generation. It has not yet been positively determined whether this anaphylactic substance can be transmitted in a strictly hereditary manner in some cases (*i.e.* present in the ovaries), or whether it is always a case of congenital or antenatal acquirement. There is positive evidence that anaphylaxis is not transmitted to the offspring through the agency of the milk. There is also conclusive evidence to show that anaphylaxis may be transmitted to the young when sensitization is accomplished either before or after the mother has conceived. It is evidently a case of antenatal acquirement in most cases and not true heredity. The question of such a transmission in man should be considered as a possible explanation of those cases of death or severe reaction following what seems to be the first injection of horse serum.

Furthermore, in this connection should be mentioned the proposition of the transmission of anaphylaxis to bacterial proteins from the mother to the young. The proteins of *Bacterium tuberculosis, Bacterium anthracis, Bacillus typhosus, Bacillus coli,* several nonpathogens and yeasts have been examined. We have here a logical and possible explanation of inherited tendencies to definite infectious diseases, as, for example, tuberculosis. There is a possibility that the so-called inherited tendency may be something more definite and specific than just a general weakened condition of the body. We, of course, deny the possibility of an inherited disease in the strict sense of the term, admitting many examples of antenatal or congenital acquirement of certain infections, as, for example, tuberculosis and syphilis.

In the anaphylaxis reaction we have the first example on record of the transmission of a hypersusceptibility to a pathological condition. There are, of course, quite a few diseases in which immunity or antianaphylaxis is transmitted to the offspring.

At this point I would emphasize the fact an individual may become immune by means of a process of hypersusceptibility or anaphylaxis. This phenomenon is undoubtedly of great importance in the prevention and cure of certain infectious diseases. The first injection of a bacterial protein into an animal produces no effect, but the second injection after an interval of time produces the same anaphylactic symtoms as horse serum. If the animal recovers, it is usually immune to further inoculations with the specific bacterial protein. We have in this phenomenon also the explanation of the periods of incubation in some infectious diseases which average from ten to fourteen days. In those having a shorter period, such as pneumonia, the crisis corresponds to the period of sensitization, and in toxic diseases such as diphtheria and tetanus anaphylaxis does not seem to be a factor.

Having thus considered the general principles of the anaphylaxis reaction, we now turn to a practical phase of the subject which has been previously referred to, namely, the cause of hypersensitization to horse serum in man. In the beginning it may be stated that few human experiments have been made. The lack of experimental material of this kind has been a block to medical progress for years. It is not definitely known how man may be sensitized, but it is evident that sensitization does take place. Notwithstanding the fact that it has been shown that guinea pigs may be sensitized by feeding them horse meat, and that in some parts of Europe horse meat is a common article of diet, it does not seem that there are any more deaths or intoxications in those countries than in this country, where we have reason to believe that horse meat is a rare article. Then, again, it is not an uncommon thing for repeated injections to be given in cases of diphtheria or tetanus, but these injections are usually large and, judging from our animal experimentation, may render the individual antianaphylactic or immune to horse serum. Von Pirquet and Schick have recorded instances of intoxication in children with horse serum after intervals of sixteen to fourteen days between injections. The first injection in these cases produced symptoms in from eight to thirteen

days, and was followed by more serious intoxications immediately after the second injection in eight to thirteen days. Currie, Goodall, Raver, *et al.* have also reported many observations of this kind. Man reacts to horse serum eight to thirteen days after the first injection. Guinea pigs do not react to the first injection, and both man and guinea pigs react to the second injection. It is possible that in the cases of fatal results the injection may have been made directly into the circulation. It is also possible that more individuals are sensitized than is commonly thought, and are not fatally intoxicated for the reason that the material was not rapidly absorbed. Rosenau and Anderson have found that dogs, rabbits, and cats occasionally normally react to horse serum. The species of these animals suggest that they may be sensitized by feeding in two instances, but in all probability some unknown chemical substance happens to be present in man and these animals and is responsible for the sensitization. Then again, the possibility of maternal transmission of hypersusceptibility should be borne in mind.

It has also been shown that there is a marked variation in the serum from different horses in regard to the power of sensitization. It may be possible that man may become immune on being fed on a certain protein just the same as by being inoculated, and this would account for the comparatively small number of reactions.

All investigations seem to show that the principal lesion of anaphylaxis is located in the respiratory center. The association of asthma and of anaphylaxis to horse serum is, of course, suggestive. It may be well to bear in mind for this reason that the injection of antiserums derived from the horse is dangerous in asthmatics. We await accurate information on the process of hypersensitization in man.

Before closing I wish to mention the pathology of anaphylaxis and one interesting application of this reaction.

Pathology of Anaphylaxis.—The lesions in the animal are quite pronounced. On opening the body of an animal killed by the second injection of a foreign protein the most observable gross lesions are the extensive congestion and petechiæ, especially throughout the abdomen. This congestion and small hemorrhages are absent in guinea pigs intoxicated by intracranial injections. These things, however, do not seem to be characteristic of the anaphylaxis reaction as they are produced by other agents. Microscopically fatty degeneration and some infiltration are observed in the heart and voluntary muscle fibers, endothelium of blood vessels, and in the nerves. There is a dilatation of the veins and capillaries, especially of the stomach and intestines, with some petechiæ. The adrenals are markedly congested, and there is also some congestion in the region of the medulla oblongata.

The Toxemias of Pregnancy.—A relation of the anaphylaxis reaction to the toxemias of pregnancy has been suggested by Rosenau and Anderson. The similarity of the symptoms and the conditions under which puerperal eclampsia occurs suggest anaphylaxis as an explanation.

The possibility of the mother being sensitized by either the proteins of the placenta or the fetal blood and subsequently being intoxicated thereby has been suggested. It is practically agreed that eclampsia is due to some toxic agent of unknown constitution, and that the placenta is the source of the toxic material. The facts that eclampsia may occur post partum and that the typical convulsive symptoms and pernicious vomiting have occurred in cases of hydatid mole (chorionic myxoma) strongly favor the placenta as the source of the toxic material. Rosenau and Anderson, who probably have investigated this subject more than others to date, call attention to the evidence which has been produced by Martin against the hypothesis of Veit, Weichardt, and others, that through the entrance of the cells of the placenta into the maternal circulation an intoxication was caused either by lysis of the cells and toxin formation or the development of toxic maternal antibodies. Rosenau and Anderson have done some experimentation to determine, first, whether the fetal blood of the guinea pig will sensitize the female guinea pig (pregnant or non-pregnant). All results were negative, which is additional evidence that the toxins are not derived from the fetus. They then proceeded to try the sensitization of the female guinea pig with autolytic extracts of the placenta of other guinea pigs. After twenty-two days these guinea pigs were again injected with placental extract, and in the large majority of cases anaphylactic symptoms resulted with marked convulsions when the material was injected into the circulation. Control animals gave negative results. It seems evident that the mother guinea pig may be sensitized by the autolytic products of her own placenta. We shall await the results of careful experimentation along this line with some eagerness.

DIAGNOSIS AND TREATMENT OF INTERNAL HEMORRHAGE AND OF PULMONARY HEMORRHAGE AS A COMPLICATION OF TUBERCULOSIS.

By THOMAS F. SMITH, M.D.,

WASHINGTON, D. C.

The subject of internal hemorrhage is one of great importance and broad range, and to take up the various forms separately would be beyond the scope of this paper. My intention, therefore, is to take the symptoms and treatment of the condition in general, making special reference only to pulmonary bleeding.

When called in to see a case of severe internal bleeding, it is usually a hurry call and we must be prepared to think and act promptly. An inquiry into the following points must be made first: Is there a history of violent trauma, such as a gunshot wound, stab wound, street car or other sudden severe accident. Is the patient as a predisposing cause suffering with any of the following diseases: Typhoid fever, malignant disease of the viscera, peptic ulcer, intestinal parasitic diseases, any of the various forms of anemia, pernicious malaria, hemophilia, aneurysm, or any constitutional disease that might cause hemorrhage? If the patient is a woman careful inquiry as to the time of last menstruation must be noted, on account of ruptured tubal gestation. The diagnosis of hemorrhage is most likely to be confounded with shock, as the two conditions present many symptoms in common, and, moreover, the two are frequently present at the same time, particularly in those cases resulting from a violent trauma. In addition to symptoms, physical signs are of the greatest importance in intraabdominal hemorrhage, and the following points are to be borne in

mind to differentiate shock from hemorrhage: In severe internal bleeding physical examination of the abdomen will reveal a bulging of the flanks, and on percussion there is a flat note, which changes with change of posture of the patient. The abdomen will be prominent, and on percussion give a highly tympanitic note. If the patient is a man there will be a collection of blood in the rectovesical pouch; if a woman, there will be found a collection of blood in the pouch of Douglas. In hemorrhage due to rupture of the spleen, as might occur in anemia, the area of splenic dullness will be greatly increased, but if the spleen is ruptured from a violent traumatism, then of course, in addition to the enlarged area of splenic dullness, the abdomen would present the signs of intraabdominal bleeding as mentioned above. If there are external wounds, the location, depth, direction, and any other characteristic should be noted, and the nature of the instrument causing the injury should be ascertained, and if possible carefully examined. In such injuries as gunshot or stab wounds, probing should never be practised, as the information gained is rarely of any service, while on the other hand serious damage may be done. The nonexistence of external wounds does not exclude internal hemorrhage in severe accidents, as one of the viscera may have been ruptured by torsion, or the trauma may have caused the rupture of an old aneurysm.

Regardless of the cause, the following symptoms of severe internal bleeding are more or less constant, some being pathognomonic:

Respiratory System—Breathing is rapid and shallow, there may be dyspnea, and the phenomenon of air-hunger is always present, and most distressing.

Cutaneous System—The skin is blanched and covered with a cold clammy perspiration.

Gastrointestinal—The mucosa of the mouth and lips is intensely pale, there is an intolerable thirst, and the lips and mouth are dry and parched. Vomiting of a thin dark fluid, which is probably altered blood, is of ill omen and is usually a forerunner of death, and is very persistent. The bowels are lost control of and the same kind of material that is being vomited will be frequently passed.

Circulatory System—The heart sounds are weak and sound distant. The pulse is extremely rapid, with a great loss of tone, the radial impulse being perhaps imperceptible. Examination of the blood shows a great loss in hemoglobin.

Nervous System—There may be frequent attacks of syncope, the mind is apathetic, there is great restlessness, the patient tosses about on the bed, and feels as though he is sinking through space. There are muscular twitchings, and perhaps convulsions. The temperature is subnormal.

Genitourinary System—Urine is voided involuntarily, and greatly diminished in quantity.

Special Senses—There is tinnitus aurium, pupils are dilated and react to light slowly, and there are flashes of light complained of. The pain sense is diminished.

Shock—As the condition of shock is due to a vasomotor paresis, there will be a great many symptoms that closely resemble hemorrhage, as will be seen by the following:

Examination of the abdomen will show no collection of fluid. There may or may not be any evidence of traumatism, as it is to be remembered that a violent mental impression frequently causes shock.

Respiratory System—Breathing is rapid and shallow, and the Cheyne-Stokes type of breathing may be present, which type usually means death.

Nervous System—There will be coma of varying degrees, from a slight transient form to the most profound which may last several days. Delirium is nearly always present and may be severe, so much so as to simulate acute mania.

Gastrointestinal—The lips and mouth are not dry as in hemorrhage. The bowels move involuntarily, or there may be obstinate constipation. There is no thirst as in hemorrhage. Vomiting is always present, and it usually marks the return to consciousness, and is not of the altered-blood appearance.

Circulatory System—The pulse is rapid and weak, there is no loss in hemoglobin.

Genitourinary—Urine is not voided, and when catheterized usually shows albumin.

Temperature is subnormal. Skin is cold and clammy. Mucous membranes are cyanotic.

The treatment of intraabdominal hemorrhage must be prompt and begin on sight of the patient.

The patient is to be first placed in bed with the foot of same slightly elevated. The pulse in my mind is the most important thing to be noted; if as is frequently the case, the pulse is strong, full and bounding, then the rational procedure is to lower blood pressure, thereby giving nature a chance to form a clot; this is best accomplished by giving at once hypodermically 1-50 gr. glonoin. But if the pulse is extremely rapid, and of a low tension, then the rapidly diffusible stimulants are indicated, such as brandy, aromatic spirit of ammonia, or ether to be given hypodermically. Autotransfusion is recommended by some with the idea of driving the blood to the vital centers in the brain at this stage of the treatment, but I am inclined to think that this procedure is not warranted in view of the fact that it will most certainly raise blood pressure, and therefore increase the hemorrhage.

In case the patient exhibits any marked nervous symptoms, ¼ gr. morphine sulphate is to be given hypodermically at once.

Having given the immediate treatment at once as above outlined, the patient is prepared in the usual manner for laparotomy, I say laparotomy as it is understood that we are dealing with a case of severe internal hemorrhage. After exploration of the abdominal cavity has been made, and the damage to vessels or viscera or both has been repaired, which must be done under the minimum amount of anesthetic and in the shortest space of time possible, our treatment changes to the exact reverse of what it has been up to this time.

The indications at this point are to replace with some fluid the amount of blood that has been lost, and to create a peripheral resistance in the blood vessels, thereby raising blood pressure, and to stimulate the heart for the great exertion it is now to undergo. Adrenalin chloride, ergot, and physiological salt solution are the three drugs we must now depend on, together with the adjunct treatment which is of the greatest importance.

As soon as the damage to the viscera has been repaired, before the abdominal wall has been closed up, from one to two pints of physiological salt solution, to which adrenalin chloride solution has been added in the proportion of one dram to the pint, should be given by hypodermoclysis. The best place to introduce the salt solution is in the loose cellular tissues of the pectoral region; the solution should be at a temperature of 110° F. as it enters the body,

and in case the absorption is very slow, another needle should be introduced into the opposite side. For this purpose another apparatus is not necessary, as two rubber tubes with needles attached, can be attached to the same solution jar. While hypodermoclysis in my mind should be the precedure of election, the condition of the patient may be such, being in collapse, that intravenous transfusion is indicated. This operation has the distinct advantage of supplying fluid to the circulation at once, but at the same time it has some dangers that cannot be overlooked. In case the fluid is introduced too rapidly there may be an acute dilation of the heart; if air should accidentally enter the vein that may cause serious trouble, although this is denied by many who have had much experience in this work; great care must be exercised that when introducing the cannula into the vein there is no clot. In intravenous transfusion the adrenalin solution is not mixed with the salt solution as is done in hypodermoclysis, but a hypodermic syringe is loaded with the adrenalin and the needle plunged into the distal extremity of the rubber tubing where it is connected to the cannula and the contents of the syringe injected in such a manner as to occupy about one minute. The solution of salt for transfusion should be at a temperature of 100° F. as it enters the vein.

While the salt solution is being introduced, whether by transfusion or hypodermoclysis, ergot is to be hypodermically injected deeply into the muscles of the thigh. This is a powerful vasoconstrictor, being in this respect identical with adrenalin, but with the great advantage that its effect is of much longer duration, from two to three hours, while that of adrenalin is at the most not over 15 minutes. Adrenalin is also a powerful direct heart stimulant, ergot is not. The injection of salt solution with the adrenalin is to be repeated every two or three hours in quantities of from one to two pints, and the ergot is to be given if indicated.

The above represents the main plan of treatment, but the symptomatic treatment is of great importance, and some of the distressing symptoms can be more or less relieved. In the first place the patient is to be wrapped in blankets and surrounded by hot-water bottles. If the respiration becomes impaired to a great extent strychnine sulphate is to be used in twentieth-grain doses hypodermically, and repeated as frequently as necessary. If vomiting ensues, nothing seems to be of any great benefit, but the sucking of small pieces of ice may do some good, as also the sipping of very hot water every few minutes; a small ice pack placed over the neck will also at times control vomiting when nothing else will. For the nervous symptoms morphine sulphate in ¼ gr. doses is very effective. For the dry and parched lips a mixture of equal parts of glycerin and lemon juice sponged on every few minutes will give much relief. The thirst is a most distressing symptom and nothing does much to relieve it, but sips of hot water may be of some service repeated every ten minutes.

Pulmonary Hemorrhage as a Complication of Tuberculosis.—While I think it practically impossible to give a satisfactory classification of the various types of pulmonary bleeding, there are at least three varieties to which I would invite attention. The first of these is not of as frequent occurrence as we would expect, when we consider the pathological changes that have taken place in the lungs. In this type the bleeding is from a large vessel that has become eroded, which traverses a large tuberculous cavity, and upon whose walls there are frequently found aneurysms.

This, as well as nearly all pulmonary hemorrhages, is not preceded by any premonitory symptoms. The exciting cause may be some violent physical exertion such as horseback riding, running to catch a car, a violent paroxysm of coughing, some great mental emotion, as joy or fear; in some cases there are absolutely no exciting causes, as the patient may be at perfect rest in bed, or may even be asleep. A hemorrhage of this kind is usually fatal in a few minutes, and the treatment is absolutely ineffectual. I have seen one such case as this in which the patient was dead in three minutes.

The second variety includes those cases in which a small vessel has been eroded, and in which the loss of blood may vary from a few ounces to a pint or more, the amount of blood lost depending on the size of the vessel and the blood pressure of the patient. The exciting causes are the same as in the class preceding this, and the symptoms will vary with the amount of hemorrhage. If the loss of blood is small, say an ounce or two, there will be no marked symptoms, other than a rapid high tension pulse, some nervousness, and the expectoration or coughing up of blood. If the loss of blood is great, perhaps a pint or more, then we have the classical symptoms of severe bleeding as mentioned when discussing internal hemorrhage. The treatment in these cases of course must be prompt, and there is usually no difficulty experienced in controlling the situation. An important point in the very beginning is our own personality; we must be able to allay the fright of the patient, reassure him by our manner that we know exactly what the condition is and that all will be well. On the other hand we sometimes come across individuals who have frequently had small hemorrhages and treat the matter very lightly. With these people we must be firm in manner, warn them of their danger, and insist on absolute rest and the carrying out of any and all orders that are given. The treatment first is to put the patient to bed, and enjoin absolute mental and physical rest. In this as well as in all other forms of pulmonary bleeding, our efforts must be first directed towards a lowering of the blood pressure, with the idea that by reducing the velocity of the blood flow we give nature a chance to form a clot at the site of bleeding. No drug in my mind meets this demand better than one of the nitrites, and as amyl nitrite is the most rapid and powerful, 5 minims may be immediately administered by inhalation; this is followed by an immediate fall in blood pressure and, in my experience, a rapid cessation of the bleeding. Morphine sulphate is indicated at this time to allay the nervous symptoms, and one-fourth to one-half grain is to be given hypodermically. Within the next fifteen minutes two ounces of a saturated solution of magnesium sulphate is to be given to produce a free watery evacuation of the bowels, which further depletes the circulation and induces an additional fall in blood pressure. These patients must be kept in bed at perfect rest for at least ten days following a hemorrhage, and should not be allowed up for any purpose whatever. They are to be kept on a light nonstimulating diet, should take a minimum of fluid, and should be given 1-100 gr. nitroglycerin three times a day. They should be thoroughly instructed as to the dangers of mental or physical exertion, and should be particularly warned as to sexual excitement.

So much for the cases of medium severity, but if the hemorrhage is great, say from two pints up, and there are symptoms of severe collapse and danger of immediate death, there is only one thing to do, we know that in hemorrhage of this degree the blood pressure is practically nil, the blood has almost ceased to flow, and that an all-wise provision of nature may have formed a clot, on the holding of which depends our only chance. The only thing to do in these cases is to give some rapidly diffusible stimulant, such as ether or brandy hypodermically, and to transfuse into a vein, preferably the median basilic or the cephalic, a pint of physiological salt solution. The transfusion of the solution must be done with the very greatest care and not too rapidly, because if the solution is introduced too rapidly we may wash away the clot, and with it our last hope. On the other hand, if the clot holds, this method will frequently save patients who are apparently moribund.

The third class of cases are those in which the loss of blood is very small, the only evidence being perhaps a blood-tinged sputum, or at the most only a few drams of free blood.

Hemorrhage of this kind is due to the erosion of small capillaries, and while in itself it will do no great damage, there may be very great harm done by injudicious treatment or advice. If in these cases it were possible to see the bleeding points, and at the same time to see the exact pathological changes that had taken place in every part of both lungs, and if we knew for a certainty that there were no cavities with large unprotected vessels traversing them, that there were no aneurysms existing, and that there was no arteriosclerosis, then the thing to do would be to give some vasoconstrictor such as adrenalin or ergot. But since we cannot be sure of the amount of damage the lungs have sustained as a result of the tuberculous infection, it would seem very dangerous to give drugs whose power to stop hemorrhage depends on their power to constrict the capillaries, because there would most certainly be a rise in blood pressure which might be great enough to cause the rupture of an aneurysm, or an unprotected vessel, and produce an immediately fatal hemorrhage. I think that under these circumstances the treatment of these cases should be the same as those in the preceding class. We should endeavor to lower the blood pressure and trust to nature to form a clot. The adjunct treatment, of course, should be rigidly carried out, such as absolute rest in bed, a light diet, free evacuation of the bowels, and small doses of glonoin.

I might add in conclusion that the lactate and chloride of calcium have both been used in the treatment of hemorrhage, and, according to some observers, with good results. The salts are given in ten to fifteen grain doses by mouth, and their administration should not be continued for more than twenty-four to forty-eight hours, as they actually decrease the coagulability of the blood if given for a longer period. The use of these drugs is, of course, for the purpose of increasing the coagulability of the blood. My own experience with calcium has been disappointing, in the three cases in which I have used it: in one of the cases the recurrence of the bleeding was greater than before.

Gelatin in solution, both internally and intravenously, is used for the same purpose as the calcium salts, some observers reporting good, some bad, and some indifferent results.

416 Second Street, N. W.

RENAL TUBERCULOSIS.*

By EDWARD QUICK, M.D.,

APPLETON, WISCONSIN.

SURGEON TO ST. ELIZABETH HOSPITAL.

In selecting the subject of Renal Tuberculosis for presentation, I had in mind the fact that there has been a great change in opinion regarding the subject during the past ten years. Perhaps some of the recent utterances of leading men are not known to you all, and I can confess freely that a rather careful study of the literature has brought to me many new notions, and has helped to clear others which I already held. The crux of the matter is this: When I was a student ten years ago, all our pathological and clinical teachers looked upon tuberculosis of the kidney as an ascending process. As it was taught there was first a genital tuberculosis, or a cystitis, then ureteritis, and later pyelitis, and tuberculous nephritis. It shall be my aim to show that the prevailing opinion to-day is that in the great majority of cases the initial tuberculosis is in the kidney, that the ureter and bladder are infected by a descending process, and that the hope of successful treatment lies in this conception of the generation, production, and development of urogenital tuberculosis.

In a critical study of the literature of any subject in medicine we are impressed with the fact that there are two distinct methods of arriving at a knowledge of the pathogenesis and pathology of a disease entity. A disease may be studied from the standpoint of pathologic anatomy as observed in the dead house. With a clear conception of a disease as seen in its end stages it is possible by a posteriori reasoning to arrive at a conception of the whole pathogenic process. However, there is great danger that fallacious reasoning will be used and consequently an incorrect concept be formed.

I am sure that you are all familiar to what extent the medical world was led astray by this method in dealing with suppurative peritonitis. For hundreds of years and after innumerable autopsies on persons dead of peritonitis the true incidence of this malady in most cases was not determined. Only until very recent years did the combined clinical and anatomical methods demonstrate that the principal sources of infection of the peritoneum are the gall-bladder, the appendix, and the Fallopian tubes. By and through the clinical method and still more specifically from the field of operative surgery, has a flood of light been shed upon pathogenesis. Of late this process of clarification has extended to the field of tuberculosis in the genitourinary organs.

From the autopsy room we secure the unfortunate term as it now appears, "genitourinary tuberculosis." This term has been long current, and carried the idea that the disease involved more or less of the entire genitourinary tract from the beginning. And when the primitive lesion was discussed the belief prevailed that the bladder was always the first organ diseased. Rokitansky lent his powerful authority to this view. As late as 1888, Guyon states, "We do not know of a single case of renal tuberculosis primitive and unilateral, without lesions of the same kind in the bladder, seminal vesicles, or other organs." It was believed, therefore, that the tuberculosis was of an ascending character, advancing from the bladder upward and therefore ineradicable. If I have reviewed the literature aright, not until

*Read before the Outagamie County Medical Society, November 10, 1908.

1897 was a case of primary tuberculosis of the kidneys reported. In the *Medical News*, of August, 1897, Dr. A. O. J. Kelly and Dr. D. D. Stewart, published an article on "The Occurrence of Primary tuberculosis of the Kidney, with a Special Reference to a Miliary Form." Little attention was paid to this communication at the time. Not until the now classic experiments of Baumgarten, of Tubingen, in 1901, did clinicians realize that there might still be something to learn about tuberculosis of the genitourinary tract. Baumgarten inoculated the urethræ in rabbits with tuberculosis and caused tuberculous ulceration of the bladder and prostatic urethra, but he was utterly unable to provoke infection of the vasa, testicles, or the upper urinary tract. These experiments were later confirmed by Giani. Baumgarten insisted that the tubercle bacilli never advanced against the current of secretion, but always with it.

What, then, are the possibilities of incidence in renal tuberculosis? Manifestly there are but three ways in which tubercle bacilli can reach such a remote organ as the kidney, viz., (1) by the blood, (2) by ascending the ureter, (3) by direct extension from contiguous organs.

Is there such a thing as a primary hematogenous infection of the kidney? It is much easier to prove that it exists than to prove that it is the usual mode of infection. Campbell, in the January Annals of Surgery, 1908, cites a case, the main features of which are these. A patient, after a long illness, with early signs of kidney involvement, underwent nephrectomy. Several months later he died of acute miliary tuberculosis. The autopsy showed all organs equally affected by miliary type of disease, but there was no old lesion that could be regarded as the source of the present miliary condition or of the former kidney lesion. The inference is therefore obvious that a primary unilateral tuberculosis of the kidney existed, and of hematogenic origin.

Campbell cites the following figures: Vigneron in 250 autopsies on subjects with tuberculosis of the genitourinary tract found 123 cases in which one kidney was intact. In practically all of these cases the lower urinary tract was involved. The same author has had 100 cases of renal tuberculosis in which only 17 had an infection of both kidneys. Tuffier reports 205 surgical cases, of which he believes 99 were unilateral and primary. Israel has a series of 21, of which he believes 16 were unilateral and primary. We may now array alongside these facts and opinions, the one other fact that uncomplicated tuberculosis of the bladder is extremely rare. Hunner reports but two cases from a large pathological experience. One of these was reported by Kelly as a case of primary tuberculosis of the bladder in the *Johns Hopkins Bulletin*, 1903. Dr. Wilhelm Karo, Berlin, at the recent International Congress of Tuberculosis, stated that bladder tuberculosis is nearly always a descending process, and that the antecedent renal tuberculosis is of hematogenous origin. Furthermore, tuberculous cystitis practically never heals when it is the point of attack for either medical or surgical treatment. But in a great majority of cases spontaneous recovery of the bladder follows removal of a primarily tuberculous kidney. These statements of Dr. Karo are his conclusions from a full clinical experience.

The arterial supply is such that the kidney structure is divided into sharply defined systems. This separation is most marked between the anterior and posterior regions, and the upper and lower poles. There is occasionally seen a sharply defined tuberculosis of one pole only. It is conceded by all that tuberculosis once started finds in the kidneys so favorable a nidus that the disease becomes always progressive. However, Mr. Henry Morris reports 7 cases of partial nephrectomy with the following results: In 3 cases total nephrectomy had to follow. Three cases were living and well 2½ years, 3¼ years and 4½ years after the operations. Such results could hardly happen unless we were dealing with primary, uniteral, definitely circumscribed renal tuberculosis of the miliary hematogenous type.

Kidneys removed by the surgeon often show a miliary type of the disease which is not part of a general miliary tuberculosis and which infection could not possibly have been distributed from the ureter. The infection corresponds to the peculiar anatomy of the kidney. The tubercles are most numerous in the cortex when the bacilli have become arrested in the terminals of the renal artery.

In the *Annals of Surgery*, November, 1908, Farrar Cobb reports 8 cases under the title "Acute Hematogenous Infection of one Kidney in Persons Apparently Well." Septic infraction of the kidney, therefore, has become a question with a very live interest, and much of real value in pathogenesis symptomatology and treatment will still be learned.

Is the kidney infected by an ascending process along the ureter? This question was affirmatively answered until quite recently, and there was hardly a thought that any other possibility existed. Let us recall Baumgarten's and Giani's experiments. In no case in the laboratory did a tuberculous infection travel against the current of secretion. Clinicians and pathologists are agreed that the ureter is seldom the seat of a true tuberculous ulceration, but that it suffers from a sclerosing, secondary inflammation.

Until this recent work on primary renal tuberculosis, a case of tuberculosis of the bladder was never cured. Direct surgical treatment was of no avail. Topical applications did no good. Scores of cases are now reported in which one kidney and the bladder were involved, and in which recovery of the bladder took place spontaneously, following extirpation of the diseased kidney. The obvious inference is that the kidney was the primary lesion, and the cystitis a descending process. There are many clinical reasons for believing that in men the disease often extends from the epididymes to the bladder, where it may involve and cause stricture of one or both ureteral orifices which, in turn, causes hydroureter and later infection of the upper urinary tract.

Direct extension from contiguous tissues must be a rare source of tuberculous infection of the kidney. Petois, in 1897, reported a case of renal tuberculosis in a girl of 19, which was the result of direct invasion from vertebral caries. While the tuberculous perinephric abscess from this source must be frequent, it would seem that the capsule of the kidney should present an effectual barrier to the active participation of the renal tissues in the process. The kidney may become a *locus minoris resistentiæ*, and have tuberculosis implanted. Newman has a series of cases in which tubercle has followed trauma. Henrotin, of Chicago, reported a case subsequent to renal calculi, which had been removed years before. There are many instances in which tuberculosis has been engrafted on hydronephrosis.

There is then considerable evidence, and a very widespread clinical notion that renal tuberculosis

is frequently, if not usually, a primary blood infection, and in many cases unilateral. However, primary has reference particularly to the genitourinary system. The actual atrium of infection must be sought in other parts of the body.

Caspar dwells frequently and with great earnestness upon the importance of a persistent acid pyuria as a diagnostic feature of tuberculous nephritis. And even a very mild grade of acid pyuria which does not yield many bacteria on the ordinary culture media should at once be placed under the category of tuberculosis somewhere in the genitourinary system. In fact, pus in the urine, which does not show bacteria in smears is very likely to be caused by a tuberculous process.

After a tuberculous infection is suspected, the hunt for the tubercle bacillus begins. If an acid-resisting bacillus is found in the mixed urines, we must determine whether this organism is the smegma bacillus or the tubercle bacillus. Both organisms are acid resisting, but the smegma bacillus is destained by alcohol and the tubercle bacillus is not. It is often useful to use the Gram stain, as the tubercle bacillus stains by the Gram method, while the smegma bacillus does not. So far as possible the smegma bacillus should be excluded by the use of catheterized specimens from the bladder.

I desire to call attention at this point to some recent work on the staining of the tubercle bacillus in which certain non-acid-fast forms are described. In cold abscesses, for example, it is usually impossible by the most careful search to find tubercle bacilli by means of the Ziehl stain, but when the Gram stain is used these non-acid-fast forms are shown.

Hans Much, who has made the most extensive contributions to this subject, was able experimentally to change an acid-fast form into a non-acid-fast form without changing the virulence of the forms. It is an interesting fact that the more virulent stains are more easily decolorized by acids. (Editorial in the *Journal of the Am. Med. Ass'n*, Oct. 24, 1908.)

Along this line there is a fruitful field for work in tinctorial bacteriology. In canvassing the literature of the subject I have many times come across the statement that pus from the genitourinary tract, which is sterile by the ordinary cultural methods, is often tuberculous, and when subjected to the biological tests, producing typical tubercle in laboratory animals. I believe, therefore, that a refinement of our staining methods would demonstrate the organisms in smears. When we have found the tubercle bacillus in the mixed urines from both kidneys, we are aware that the infection is somewhere in the urinary tract, and the problem to point out its exact location is a most important and difficult task. The modern cystoscope, whether we use the Nitze instrument or the Kelly air inflation-direct method, is essential in bringing the facts to the fore. We first note the extent of bladder involvement. If the infection is not recent the characteristic appearance of ulceration and tubercles present more or less extensively over the bladder mucosa. The ureteral orifice will show a reddened, swollen appearance known as the "bullous edema" of Caspar, or the orifice will be retracted, the golf-hole ureteral orifices of Mr. Hurry Fenwick. The retraction is due quite as often to a secondary sclerosing inflammation as to actual tuberculous involvement of the ureter. It may be possible to secure a working diagnosis with the conditions determined by the cystoscope and with other clinical data. If not, the question of ureteral catheterization must be considered. This is a bit of technique that is not easy nor is it without its dangers to the patient. There has been much abuse of the ureteral catheter, notwithstanding its enthusiastic advocacy by some men who have made it popular. Catheterization of healthy kidneys through known infected bladders is a dare-devil procedure and not to be tolerated. I make this assertion with full knowledge that Howard Kelly advocates double catheterization and practices it with impunity, and states that he has never seen any ill effects. But I note in Hunner's article in the *Johns Hopkins Bulletin*, 1904, Case 2, a patient had both ureters catheterized eight years before. There was no evidence of bladder tuberculosis, nor of either ureter. The urine from left kidney was negative. Unilateral tuberculosis of right kidney was diagnosed and the kidney removed. At the time of the report the patient showed symptoms of infection of the only kidney. Is it not a fair question to ask, Was not the left kidney infected by the ureteral catheter? I believe the practice is dangerous. We know the bacilli are in the bladder, and, in some cases at least, must be carried into the healthy ureter and kidney. The passage of the catheter often causes bleeding. Traumatic bleeding and bacteria constitute too great a risk for the only healthy kidney. Catheterization of the supposedly healthy side is unnecessary. Catheterize the diseased side. While this is draining and the bladder is washed out, what collects in the bladder represents for practical work the urine of the other side. The diseased side will be indicated usually by swelling and tenderness of the diseased kidney.

The presence of tubercle bacilli in the urine is of the highest importance. The absence of the organisms is not so vital. Their presence may give rise to great difficulty in diagnosis, since it must be borne in mind that tubercle bacilli as well as many other organisms may pass through the kidneys without infecting them. Henry Morris performed nephrectomy on a patient having a large tumor in the right renal region. Tubercle bacilli were found in the urine on repeated occasions. No tuberculosis of the kidney could be found, but it was the seat of calculous pyonephrosis. There was a mass of enlarged glands above the left clavicle and the patient subsequently died of tuberculous pleurisy. Tubercle bacilli are often absent in cases of primary renal tuberculosis.

I have had no experience with the Harris instrument. Other than Dr. Harris himself, I have not met an enthusiastic advocate of it. In his hands the instrument must render efficient aid, for he can wield it with the hand of a master.

If both kidneys are infected with the tubercle bacillus we can only wait for death to relieve the burden. A spontaneous cure is so rare that Albarran could successfully challenge the French Surgical Society to produce an indubitable instance. Tuberculosis of the kidney assumes the aspect of a malignant infection. It is with the rarest exceptions progressive. To attempt a cure by climatic and hygienic measures is time lost. If both organs are involved, of course, this is the only method available. When one organ is infected, to postpone surgical intervention is to court the risk of infection of the bladder and sister organ. A seeming cure is sometimes obtained by the process of caseation and final sequestration through obliteration of the ureter.

When we are dealing with a unilateral renal tuberculosis we have an affection incompatible with health, and in the end destructive of life. The disease is located in a paired organ, one of which can be readily spared by the economy. The only reasonable indication seems to me a radical extirpation.

IS GASTROINTESTINAL AUTOINTOXICATION A DISEASE OR ONLY A SYMPTOM?*

By O. L. MULOT, M.D.,

BROOKLYN, NEW YORK.

LATE INSTRUCTOR IN DIAGNOSIS AND ATTENDING PHYSICIAN IN THE DEPARTMENT OF MEDICINE IN THE UNIVERSITY AND BELLEVUE MEDICAL COLLEGE DISPENSARY.

THE interest in gastrointestinal autointoxications is growing and its importance to the physician and surgeon is daily being more generally realized. It requires only a short perusal of the findings of those who have investigated the bacterial flora of the intestines to become convinced that there is a rich field from which trouble may come. Bacteriologists are not agreed as to the number of varieties of microorganisms habitual to and usually present in the bowel. How varied is this intestinal flora may be judged from the estimates given by the bacteriologists who have investigated this question. Matzuschka has isolated forty-four varieties; Miss Tsiklinsky has shown that this number increases when cultivated in a high temperature. As to quantitative figures, Vignalt and Suckdorf estimated that each day the adult body gets rid by the dejecta of from thirty-nine to fifty billions of microbes; Gilbert and Domenici estimate the figure at twelve billions, and state that these figures may be lowered to one hundred and sixty-four millions by an exclusive milk diet. Klein of Amsterdam gives it at eighty-eight hundred billions; but this figure is evidently too high. While it is admitted by all who have busied themselves with the intestinal bacteria, that less than two per cent. of the quantity passed are alive, we must not forget that even these dead germs represent toxins with which the body must deal; and when we further consider that these figures represent nearly two drams by weight of solid bacteria, we can realize what a formidable menace any disturbance of the equilibrium here may constitute, if not in all cases an actual menace to life, certainly one to health and well being. Yet in spite of these factors there are many who hold high rank in the profession who still try to dismiss the subject of gastrointestinal autointoxications by a wave of the hand. In one of the systems of medicine, recently put on the market, under a highly honored editorship, the whole subject is accorded a scant page and a half. Herter's work along this line has certainly placed the subject among those meriting most serious consideration.

The viewpoint indicated by my title is not entirely new, but a fairly comprehensive search of the literature revealed such a paucity of English, and practically nothing in American literature on this aspect, that I feel no need of an apology on my part for its presentation. There is a vast literature on gastrointestinal intoxication but most of it is scattered through the journals; until recently no English text book was available. The capital work of Combé, which was published in Paris in 1907, is now undergoing translation. Then there is Herter's small manual.

Before endeavoring to answer the title, it seems but right that we should have some idea of what is to be considered under gastrointestinal autointoxications. A term that covers the whole tract from the cardia to the anus can be made to include much; but many diseases whose pathology lies in this extensive tract may be excluded from consideration here. We are not now concerned with the acute diseases of this tract, whose clinical picture, etiology, and pathology are so familiar to us all, but rather with chronic conditions, often vague and indefinite in symptomatology, but making the patient so miserable. Herter has proven that these intoxications are responsible for certain forms of pernicious enemia. That the liver plays an important part in these anemias and its relation with indicanuria was realized in a communication to the International Congress, Paris, 1900, by Gilbert and Garnier. Herter does not refer to this in his bibliography.

Sahli recently has stated that indican is present in the urine only when the pancreas is healthy. I want to state that gastrointestinal intoxication is possible without indican and with a perfectly healthy pancreas, or at least so judged to be by the complete digestion of nuclear tissue, as shown by an examination of the feces after a copious meal of underdone sweetbreads. Those who believe that there can be no gastrointestinal autointoxication without indican in the urine will overlook many cases.

There has been no evidence produced that these chronic gastrointestinal intoxications are due to a special pathogenic organism accidentally introduced and stranger to the tract. Our figures have shown that there are more than enough ever present to cause mischief.

What then must occur that one variety or several or all of them become a source of trouble? Why does not everybody suffer from this trouble? This is the pertinent question. Let us go back to our physiology of digestion and review the various juices and their properties, with which the bolus must come in contact on its journey from the mouth to the anus. We will not waste time on the saliva and the gastric juice. In the duodenum, at the site of the common duct, it encounters the bile and pancreatic juices. We were formerly taught that the bile was antiseptic; then we were told that its antiseptic power was only very slight, in fact almost nil and negligible. The question is what variety of bacteria was used to determine the bactericidic power of the bile? The most resisting and then on down through the varieties of lesser resistance. This does not seem to me to have been a wise procedure. Did nature intend this secretion to combat such virulent germs? Would it not be more in keeping with physiological conditions and requirements to test the power of the bile action upon such germs as are habitually present in the bowel? These are the ones that cause the trouble; these are the ones that the antiseptic power of the bile should be judged by. Is it necessary that this antiseptic power kill germs or will nature's purposes be attained if their growth be retarded within certain innocuous limits? This latter would seem to be quite sufficient for health.

Is it then a question of quantity or of quality of bile? The answer still lies in the future; it belongs

*Read at the Brooklyn Medical Society February 10, 1909.

in the domain of the still unknown. Probably both are at fault. The physiology of the liver is far from complete and while the future will add little to the cellular pathology of this organ, its functional pathology is destined to become more and more the subject of research, and with it the bile.

That there is a functional pathology becomes evident when one studies that most masterly article on diabetes by Richardière and Sicard in the "Nouveau traité de Médecine et de Thérapeutique," published under the editorship of Brouardel and Gilbert. In that article the writers refer to the interesting communication of Gilbert, Professor of Therapeutics at Paris, and his pupil, Weill, which appeared in the *Semaine Médicale*, November 15, 1899, "on a diabetes due to chronic hepatic insufficiency." This highly interesting article sheds some important light on liver functions; the gastrointestinal disturbances, such as foul irregular stools, flatulency, and the indicanuria and urobilinuria which are present in this form of diabetes are important to my argument. Under the head of treatment they find occasion to refer to another communication of Gilbert and Carnot, International Medical Congress, Paris, 1900, giving the result of treatment of this form of diabetes, by a liver extract, which resulted in a marked diminution and in some cases the entire disappearance of sugar; but what is more pertinent to my subject is the disappearance by this method of treatment of the gastrointestinal disturbances.

I have studiously avoided a detailed description of this form of diabetes. It is hard to resist dipping into these French views on this disease, so sound and alluring and having so much inherent proof of correctness; but I must stick strictly to my subject, as it was from a study of these writings that the idea came to me that the whole question of gastrointestinal intoxications is a matter of liver function, and led me to search the literature. Before going into the literature, let us see if there are any other proofs that we can bring in support of this contention. In the summer diarrhea of children we give calomel and its action is variously explained as due to an antiseptic action, or to the flushing out of the bowel, ridding it of bacteria and toxins, but entirely disregarding any action that calomel may have on the liver, and a disinfection of the bowel due to an outpouring of bile. I know that this action of calomel is denied by the pharmacologists; but clinical evidence is not to be entirely disregarded. There is still another drug, one that will not involve us in an argument with the pharmacologist; podophyllin. This drug acts well in adults and it has never been endowed with antibacteric powers by the pharmacologists.

Herter has pointed out how difficult it is to obtain anything like a permanent result in the treatment of these conditions. It is then clearly desirable that the reports of liver extract medication be verified by more extended use, and if proven correct, would entirely revolutionize the treatment. I have been unable to find any report of the use of liver extract in this country.

If, then, gastrointestinal intoxications are only a symptom of hepatic insufficiency, our interest in the various bacteria of this tract will become purely academic. If we accept this as a fact, we naturally ask ourselves the next logical question, what causes this liver insufficiency? At present it cannot be answered by more than a shrug of the shoulders. Carnot believes that ascending infections is responsible. I cannot share this opinion, for it certainly seems that something must have preceded to make this possible. Speculation points out a direction in which search may be made for the answer to this question. The products of pathological digestion; what are they? Do they differ from those of normal digestion? If these products differ from the normal how do they affect the economy? Oxalic acid, oxaluria, acetone, ammonium butyrate, cholin, neurine, marcaptan, and hyrogen sulphide; are these causes or results? May we not have from this source leucomains that stimulate or depress certain organs, directly or through central nervous system? This represents a field almost virginal upon which we have practically no information. Dilated stomach has so often been found associated with certain forms of arthritis deformans and chronic rheumatism as to preclude the idea of simple coincidence. If these dilated stomachs, with their illy digested, foul smelling, fermented contents, can give rise to a substance that can produce changes in bone ends and articular surfaces, would it then be such a wild flight of fancy to suspect that from this source might come other deleterious substances?

In spite of the fact that stomachs are being washed every day and analyses of contents are daily made by specialists, these men have contributed practically nothing to this question of the products of pathological digestion. They have contented themselves with making routine examinations of the long known elements, never seeking anything new. I firmly believe that when this chapter shall come to be written in its entirety, then we will know the true etiology of such diseases as uric acid diatheses, arteriosclerosis, gout, diabetes, and obesity.

Changes in the Spleen and Pancreas in Hepatic Cirrhosis.—A. M. Luzzato, as a result of histological examinations, states that in hepatic cirrhosis there are changes in the pancreas consisting of increase of perilobular and periacinous connective tissue without evidences of inflammation. In advanced cases there is destruction of the acini, but not of islands of cells. In the paronchyma there is necrosis in part due to autodigestion. There is also proliferation of the centroacinous cells and hypertrophy of the acini. There is a true return to the embryonal conditions. There is no relation between the amount of changes and the stage of cirrhotic disease of the liver. In the spleen there is blood stasis and in late cases sclerosis of the follicles. There is no proportion between the intensity of the lesions in the spleen and liver. These findings argue against the supposition that cirrhosis of the liver is a local disease, and in favor of its being a general disease.—*La Riforma Medica.*

THE POTENTIALITIES OF RADIUM AS A CURATIVE AGENT.

RADIUM has now been employed by the medical profession for a period sufficiently long to warrant the expression of fairly definite opinions as to its merits from a medical standpoint. At first, as is always the case with novel remedies, exaggerated curative powers were claimed for the substance discovered by Madame Curie, assisted by her husband. At the present time it would be quite within the bounds of truth to say that the medical world is divided into two camps so far as views regarding the efficacy of radium as a curative agent are concerned. Among some medical men great scepticism exists with regard to the healing properties of radium. It has been boomed by the lay press, and to a lesser extent by a section of the medical press, as a certain panacea for almost all the physical ills to which flesh is heir. On the other hand, noted pathologists have gone so far as to maintain that there is no single disease to which this type of remedy has been applied in which it also has not been regarded as a failure. Of course both these expressions of opinion err on the side of exaggeration, for while no results have shown that radium is by way of being a universal cure-all, neither have its remedial properties proved wholly abortive.

Much of the prejudice that undoubtedly remains in the minds of many medical men against radium is on account of the unskilful employment of the same. The fact must be borne in mind that the ordinary practitioner is not competent to use radium as it should be used, and if he endeavors to apply it the results will assuredly be unsatisfactory. A man to administer electric treatment, light treatment, or radium effectively must be qualified for his work by proper technical training. Cures have been made by radium in cases of rodent ulcer, and great hopes were built upon radium in the treatment of cancer. In deep-seated cancer it has been of little use and its administration in cases of epithelioma has not always been attended with positive results.

The beta rays emitted by radium are said by Treves to have insufficient penetrative power to be of service in the treatment of malignant disease, but for this reason are valuable for skin affections. Pigmented moles, hairy moles, and birth marks are readily amenable to treatment by radium, and chronic eczema has been found frequently to yield to the same remedy.

The potentialities, then, of radium as a curative agent are partially gauged, but much further knowledge of the subject is required before it would be wise to make dogmatic statements. What is most needed just now is a thorough scientific study of the matter. In England such study is about to be entered upon. The King and Queen of England have always shown themselves peculiarly interested in methods calculated to destroy or restrain cancerous growths, possibly because several of the King's close relations have suffered from malignant disease. The Queen was mainly instrumental in establishing the magnificent light installation for the treatment of certain diseases at the London Hospital; King Edward has now taken the initiative in founding a radium institute in London. It is true that the necessary funds have been found by two rich men, but the suggestion that London should have a radium institute emanated from the King. The intention of those responsible for the evolution of the scheme is that at the institute both necessitous and well-to-do patients will be treated—the former free and the latter at reasonable fees. It is designed for curative as well as research purposes, and in this respect differs from other radium institutes which are intended solely for research.

In order to show the pressing need of scientific investigations into the curative powers of radium, a quotation from some remarks recently made by Sir Frederick Treves will suffice. He said that to administer radium from a tube instead of from a flat surface was ridiculous, on the ground that the operator could not know what he was doing. On the other hand another distinguished English physician, one who was a pioneer in the medicinal use of radium, has stated that in his opinion the administration from the glass tube was the most satisfactory of the present methods. Abbe of this city has also had almost marvelous results from radium treatment, using the remedy in tubes.

Nevertheless, the therapeutic employment of radium, indeed, has hardly advanced beyond the empirical stage. It is known, or at any rate is a matter of common belief among a very large number of the medical profession, that the material particles ejected from the radium, or the waves set up in the ether, have a beneficent influence upon some diseases. It is felt that the potentialities of radium, chemical, physical, and medical, are of great value. The question is how to estimate the amount of its value. These questions the Radium Institute will carefully investigate and it is to be hoped answer successfully. The rarity, and consequently the very high cost of radium has been against its general use. With the exception of certain mines in Bohemia, England is said to be at present the only source of supply of pitchblende from which, after the extraction of uranium, radium is produced. It is proposed to utilize the large quantities of pitchblende known to be in the south of England, and if the endeavor thus to obtain radium in large amounts is successful, the price of the substance will be materially decreased, to the benefit of all concerned.

TUBERCLE BACILLI IN THE CIRCULATING BLOOD.

That tubercle bacilli are often transported by the blood-stream from some local focus of infection has been the common belief of all pathologists; indeed, this phenomenon is the probable explanation of the occurrence of acute miliary tuberculosis in patients suffering from a localized tuberculous inflammation ending in caseation and the discharge of infecting material into some neighboring vessel. On the other hand, the more usual forms of tuberculosis, and especially the chronic pulmonary form, have never been looked upon as diseases accompanied by frequent presence of the bacilli in the circulating blood. It is not surprising, therefore, that a sweeping statement made by Dr. Rosenberger in the *American Journal of Medical Sciences*, for February, 1909, claiming that all forms of tuberculosis are characterized by a bacteriemia, should meet with incredulity. We quote the words of the author in reference to the findings in examining specially prepared blood films in tuberculous patients: "In every case examined tubercle bacilli were found. Sometimes only a few were seen, but they were mostly in large numbers, and clumps of thirty to forty bacilli were not unusual, especially in the cases of acute miliary tuberculosis."

It would seem that other workers should be at least occasionally successful in finding tubercle bacilli in the blood according to the method of Dr. Rosenberger, his technique being simple and his results so uniformly positive. Yet the attempts to corroborate Dr. Rosenberger's findings made in two large hospitals of New York have been uniformly unsuccessful. The article of Dr. Rosenberger, too, does not state whether any control examinations were made with normal blood to exclude the possibility of artefacts being mistaken for tubercle bacilli; anyone who has stained sputum knows that clumps of red stained granules are often found in such specimens, which resemble tubercle bacilli by keeping the red stain in spite of decolorization with acids. Such granules seem to be particles of cell detritus and when the enormous numbers of the "shadows" of red cells that must have been present in the films made according to Dr. Rosenberger's method are remembered, the suspicion is justified that they may have something to do with the microscopic appearances described by that author. Moreover, animal inoculations are, of course, the last means of appeal in demonstrating the presence of tubercle bacilli in tissues; Dr. Rosenberger mentions only two inoculations of this character, a single animal being used in each case!

It is notoriously unsafe to deny the possibility of any achievement in science or human endeavor, and there can be no doubt that the question brought up by the author is of interest to all workers in tuberculosis. The published results, however, require much more corroboration than the author has seen fit to procure or to mention in his article. As the matter stands, one may well class the surprising data given by Dr. Rosenberger among the "important, if true" findings which appear so frequently in modern literature of medicine.

POSTOPERATIVE SITTING POSTURE.

Surgeons no longer insist that a patient should be kept flat on the back for many days after an operation, as it has been abundantly proved that such a position in certain individuals is attended with grave danger of postoperative complications. No graver danger than hypostatic pneumonia can threaten a patient after a successful aseptic operation, and this is precisely the condition to which the flat position in bed predisposes old or very obese individuals. On the other hand, it has been shown that the peritoneum of the upper abdominal cavity absorbs much more rapidly than the pelvic peritoneum, and in case toxic material is present in the peritoneal cavity, the flat position offers a distinct chance for overwhelming the body with the toxins. These and similar conditions are considered by Dr. Willis D. Gatch, who writes on the advantages of the upright position in the *Annals of Surgery* for March, 1909. The difficulty in maintaining the upright position has been, however, that it was effected by simple back rests which did not prevent the patient from sliding down in bed. In such a case, the upper peritoneum was suddenly exposed to the toxic material gathered in the pelvis and the patient was in no way benefited by the temporary upright position. The author thinks hospital wards ought to have a number of beds provided with suitable arrangements for procuring an upright posture for the patient, and he describes a simple device of this sort adopted in the Johns Hopkins Hospital.

Dr. Gatch has found the upright position a distinct advantage not only in peritoneal conditions, for which Fowler first recommended it, but likewise in cases where continuous draining or irrigation is employed, the effect of gravity helping very much the proper continuation of these procedures. Moreover, in many purely medical conditions the device for obtaining an upright position is found extremely useful, patients with advanced heart disease or orthopnea from whatever cause being distinctly benefited by being placed in a comfortable semi-inclined position. Dr. Gatch concludes that in most cases cause must be shown for keeping a patient lying rather than for making him sit up. It certainly seems reasonable to allow the patient to assume the sitting posture much earlier than is usually done.

Intraabdominal Use of Oxygen.

Oxygen as a respiratory stimulant has been quite often used in pneumonia and in cyanosis of whatever nature. Beyond this the gas has not found much popularity either with physicians or with surgeons. That it may be advantageously employed in many surgical conditions is shown, however, by the results obtained by Dr. William S. Bainbridge, described by him in the *Annals of Surgery* for March, 1909. He has employed the gas in a novel way, allowing it to fill the abdominal cavity after laparotomies, the tube carrying the oxygen being inserted into one corner of the wound. The experience with this method in thirty cases showed that oxygen administered in this fashion distinctly

lessened postoperative shock, hemorrhage, nausea, and vomiting; it overcame the dangerous negative pressure in the abdomen resulting from the removal of large tumors; it prevented or diminished the tendency to the formation of adhesions. In a few cases of tuberculous peritonitis it seemed to add to the curative action of simple laparotomy, and in septic peritonitis its use was followed by distinct improvement in the symptoms. Dr. Bainbridge's method consists in ballooning the abdomen with the gas and then closing the wound, thus allowing the tissues to absorb the oxygen gradually. It is, therefore, quite different from "flushing" the abdominal cavity with a large quantity of gas which is allowed to escape freely, or from the employment of hydrogen peroxide which leads to the formation of nascent oxygen within the cavity. Whether the favorable results described by Dr. Bainbridge were due to the method of the administration as much as to the action of the gas itself remains to be shown by further work in the laboratory and on the operating table.

News of the Week.

Sanitation of the Canal Zone.—The chief sanitary officer of the Isthmian Canal Commission, Dr. William C. Gorgas, has presented a report for the year 1908. Among the employees alone the death rate was 13.01 per thousand for the year, a remarkable decrease from 1906 when the rate was 41.37 and from 1907 when it was 28.77. The total number of deaths among employees during the year was 571. It is also particularly interesting to note the decrease in the death rate among the blacks. This was 47.24 in 1906; 33.28 in 1907; and 12.76 in 1908. During the year there were 2,674 American women and children on the isthmus, and among these the death rate was only 9.72. As has been the case in past years a large proportion of deaths were due to pneumonia; but even here there was a large decrease, the figures being 431 deaths in 1906, 328 in 1907, and 93 in 1908. There were 38 deaths from beriberi during the year. The number of cases of malaria is taken as a reliable indication of the general health conditions and of the efficiency of the sanitation. In 1906, out of every thousand employees, 821 were admitted to hospital suffering from malaria; in 1907, 424; and in 1908, 282. In other words, there is now only about one-third the amount of malaria among employees that there was three years ago. It is now more than three years since a known case of yellow fever has developed in the isthmus; the last case of plague occurred in August, 1905.

New York's Death Rate.—For the week ending March 21, the death rate in New York showed, for the first time in many months, an increase over the rate for the corresponding week of the preceding year. The rate for 1908 was 17.46 per thousand, while in 1909 it was 18.07, the total number of deaths being respectively 1,480 and 1,581. There was an increase in the number of deaths from heart disease, pneumonia, tuberculosis, and Bright's disease. Among infants under one year of age there were 305 deaths as against 279 in 1908.

Yellow Fever Decreasing.—The recent epidemic of yellow fever in Barbados is gradually disappearing, fewer cases being reported each day. The local health authorities have been assisted in fighting the disease by Sir Rupert Boyce of the Liverpool School of Tropical Medicine.

Ether as a Fake-Exposer.—A novel experiment was made in Hoboken, recently, according to newspaper story, when a man, arrested for soliciting alms as a deaf mute, and suspected of shamming, was put under the influence of ether in St. Mary's Hospital. His free use of speech while he was recovering from its effects cleared up all doubts as to his ability to hear and speak.

Regulation of Opium Importation.—The recent act of Congress prohibiting the importation of opium except for medicinal purposes becomes effective on April 1, and the Treasury Department has issued rules of the most stringent character to provide for its enforcement. The term "opium" is considered as covering all forms known to the trade. In connection with this law the Bureau of Chemistry is also investigating a number of "opium cures" which are being widely sold, many of which, of course, are only fakes, and contain a dangerous percentage of morphine.

Ambulance Wrecked.—A New York Hospital ambulance responding to a call in West Thirtieth street on March 27, was practically reduced to kindling wood by a collision with a Sixth avenue street car. Both the ambulance surgeon and the driver were slightly hurt.

Class for Consumptives.—The work of the Bellevue Tuberculosis Clinic has been extended somewhat along the lines of the classes for patients which have proved helpful elsewhere in New York and in Boston. A class, at present consisting of fifteen patients, meets each Monday afternoon on the old ferryboat *Southfield*, when progress is reported and encouragement given.

Federal Sanatorium.—A bill providing for the establishment in Colorado of a sanatorium for the treatment of tuberculosis, to be conducted by the Federal Government, was introduced into the House of Representatives recently. The bill provides for an appropriation of $2,500,000 for the purpose.

Improvements at Bellevue Hospital.—Plans have been filed with the Building Department for remodeling and enlarging the Marquand Pavilion, known as Ward 31, of Bellevue Hospital. The improvements include the installation of a new plumbing plant and the inclosing of the verandas with glass partitions. Wards 18 and 25, which connect with the Marquand Pavilion, will also be somewhat remodeled.

Hospital for Ruptured and Crippled.—An appeal for aid for this institution has recently been made, because of a deficit of $29,711 in the running account for the past year. During 1908, 967 patients were treated in the hospital and 12,963 in the dispensary. A total of 340,000 patients have been treated since the establishment of the hospital in 1863.

Children's Free Sanatorium.—Through the generosity of Mrs. A. A. Anderson of New York, the Children's Aid Society has recently been able to establish a sanatorium for the treatment of ill and crippled children on Chappaqua Mountain, Westchester County, N. Y., to be known as the Chappaqua Mountain Sanatorium of the Children's Aid Society. The institution which will be open for patients on June 15, will be in commission during the entire year.

Hospital Legislation.—The New York Legislature is considering a bill providing for the establishment of an ambulance service to cover the entire city of New York, the supervision of the service in Manhattan and the Bronx, except for that which is under the control of the Department of Health, to be placed under the trustees of Bellevue and Allied Hospitals. In the other boroughs the supervision is to be exercised by the Commissioner of Public Charities. The position of director of ambulances is provided for the direct overseeing of the work.

Another bill introduced into the Legislature this year authorizes the Department of Health of New York City to assume exclusive charge and control of hospitals for the treatment of contagious, pestilential, or infectious diseases.

Charitable Bequests.—By the will of the late William Y. Meschter of Norristown, Pa., the following bequests are made: Franklin Reformatory of Inebriates, $200; Pennsylvania Society for the Prevention of Tuberculosis, $300; Medico-Chirurgical Hospital for the endowment of a free bed in memory of his father and mother, $5,000; Methodist Episcopal Hospital, $500.

The promised donation of Mr. William Deering to Wesley Hospital, Chicago, of $55,000 is subject to the raising of a similar amount by the board of directors, the entire $110,000 to be used for the completion of the building, according to the original plan.

Mr. Peter Quackenbush of Paterson, N. J., has donated $40,000 to build a home for the nurses in the Paterson General Hospital, of which he is a director. About a year ago Mr. Quackenbush gave $10,000 to buy the site for the home.

The Bellevue Hospital Alumni Society held its annual banquet at Delmonico's on March 24. Mayor McClellan spoke in praise of the work and devotion of the physicians, and addresses were also made by Dr. J. H. Woodward, president of the society, the Rev. Nehemiah Boynton, Dr. S. Alexander, and Mr. L. F. Brown.

Association of American Physicians.—The twenty-fourth annual meeting of this association will be held in the New Willard Hotel, Washington, D. C., on May 11 and 12, 1909. Dr. Victor C. Vaughan will deliver the president's address and a long and interesting programme has been arranged.

The Florida Medical Association.—The thirty-sixth annual meeting of this association will be held at Pensacola, Fla., on April 7, 8, and 9, 1909. Dr. J. D. Love of Jacksonville will deliver the public oration on the evening of April 7. Dr. J. F. McKinstry, Jr., of Gainesville is the president of the society, and Dr. J. D. Fernandez of Jacksonville, the secretary and treasurer.

Pawtucket (R. I.) Medical Society.—The annual meeting of the society was held on March 18, when the following officers were elected for the ensuing year: *President,* Dr. B. L. Towle; *Vice-President,* Dr. Byron U. Richards; *Secretary,* A. R. V. Fenwick; *Treasurer,* Dr. M. A. Ford; *Delegates to State Medical Society,* Drs. C. A. Stearns and W. F. A. Gillen.

American Academy of Medicine.—The second mid-year meeting of the American Academy of Medicine was held in Chicago, Ill., March 25, at the Auditorium Hotel, it being a conference with academic and medical teachers. In the absence of the president (Dr. Helen C. Putnum) the first vice-president, Dr. Charles S. Sheldon, Madison, Wis., occupied the chair. Dr. Colwell, Secretary of the Council on Medical Education of the American Medical Association, stated the entrance requirements and the didactic and laboratory portions of the medical course of those colleges whose entrance standard requires one or two years of study after the completion of the high school course. Dr. Walter McNab Miller, Columbia, Mo., discussed the question, "Can the third and fourth years of the literary college give any of the subjects in the medical course?" Dr. John L. Heffron, Syracuse, N. Y., read a paper entitled "Can the College Give in the Junior and Senior Years as Elective Any of the Subjects Required of a Student in His First Two Years in a College of Medicine?" These papers were freely discussed by several members. At the afternoon session, Dr. Charles McIntire, Easton, Pa., read a paper entitled "What Are the Underlying Principles Permitting the Accepting of Students to Advanced Standing in a Medical College, and What Method Should be Used to Make These Principles Effective?" Dr. Edward Jackson, Denver, Col., presented a paper entitled "Preliminary and Graduation Requirements for the Medical Course in Terms of Work Done."

Society of Sanitary and Moral Prophylaxis.—At the regular meeting of this Society, on April 8, the general subject for discussion will be: "Blindness of the New-Born and Its Prophylaxis." (1) From the standpoint of the Eye Specialist, by Dr. Charles Stedman Bull; (2) from the standpoint of the Obstetrician, by Dr. James Clifton Edgar; (3) from the standpoint of the Sanitary Officials, by a representative of the Health Department of New York City.

Mississippi County (Ark.) Medical Society.—At the annual meeting of this society, on March 9, the following officers were elected: *President,* Dr. S. A. Lowry of Luxora; *Vice-President,* Dr. H. T. Crawford of Wilson; *Secretary,* Dr. Oleander Howton of Osceola; *Treasurer,* Dr. W. H. Hudson of Luxora; *Delegates to State Society,* Drs. H. C. Dunavant and D. C. Joyner.

Twenty-sixth German Congress for Internal Medicine.—The sessions of this congress will be held in Wiesbaden on April 19 to 22, 1909. Full information as to program, etc., can be obtained from Dr. Emil Pfeiffer, Parkstrasse 13, Wiesbaden.

Sixth French Congress of Gynecology, Obstetrics, and Pediatrics.—The sessions of this congress will be held in Toulouse, France, from September 22 to 27, 1910, under the presidency of Professor Kirmisson, who is also the president of the section of pediatrics. Professor Hartmann will act as president of the section of gynecology, and Professor Rouvier of Algiers of that of obstetrics. Applications for places on the programme should be addressed to the Secretary General, M. Audebert, Professeur de Clinique Obstétricale, 1, place Matabiau, Toulouse.

Medical Legislation in Connecticut.—Among the important bills now before the Connecticut General Assembly is one providing for the establishment of a State colony for epileptics to be maintained at public expense. Another bill makes it unlawful for any public board in the State to compel the vaccination of any infant, or to make vaccination a condition precedent to attendance at any

public or private school. A third bill provides for the registration of those engaged in the practice of optometry.

Philadelphia Municipal Appointments.—Dr. C. A. Groff, for many years an assistant medical inspector, has been appointed assistant chief medical inspector in the Bureau of Health, in succession to Dr. Thomas J. Beatty, deceased, and Dr. William Drayton, Jr., formerly resident physician in the Municipal Hospital, has been appointed assistant medical inspector, in succession to Dr. Groff.

Dr. Alvin W. Hewlett, assistant professor of medicine in Cooper Medical College, San Francisco, has been appointed to succeed Dr. George Dock, as professor of medicine in the University of Michigan.

Dr. Charles Karsner Mills of Philadelphia was the guest of honor at a testimonial dinner in that city on March 13, the occasion marking the fortieth anniversary of his entrance into the medical profession. Addresses were made by Dr. S. Weir Mitchell, Dr. James J. Putnam, Dr. Abraham Jacobi, Dr. William H. Welch, Dr. Charles L. Dana, the Rev. Arthur B. Conger, and Provost Harrison of the University of Pennsylvania. A silver loving cup was presented to Dr. Mills by Dr. W. W. Keen on behalf of those present. Dr. George E. de Schweinitz acted as toastmaster.

Dr. Richard C. Cabot of Boston spoke at Smith College, on March 17, on "The Human Side of Hospital Work."

Hereditary Syphilis and Epilepsy.—Dr. William P. Spratling, 1110 N. Charles street, Baltimore, requests information concerning cases of epilepsy in children in which the cause seems to be cerebral syphilis in either of the parents.

The Late Dr. Murray.—At a regular meeting of the New York Medico-Surgical Society, held at the Hotel Manhattan on the evening of March 20, the following resolutions were unanimously adopted:

Whereas, death has removed from the roll of this society, on February twenty-seventh, one thousand nine hundred and nine, our friend and colleague, Dr. Robert A. Murray, and

Whereas, during the many years of his membership in this society, Dr. Murray has been a most active and enthusiastic supporter of the objects which brought about the organization of this society; and

Whereas, by his regular attendance and active participation in discussions on all subjects brought before the society, as well as by his sociality, he has added much to the interest of our meetings, be it

Resolved, That in the death of our friend and fellow member, the New York Medico-Surgical Society has sustained a great loss in one who, by his sympathy, geniality, and untiring devotion, was endeared to all; be it further

Resolved, That these resolutions be spread in full upon the records of the society, a copy sent to the medical journals of this city for publication, and an engrossed copy transmitted to the family of our deceased colleague.—J. Arthur Booth, M.D., T. K. Tuthill, M.D., John A. Bodine, M.D., Committee.

The following minute was adopted at a meeting of the Northwestern Medical and Surgical Society: The Northwestern Medical and Surgical Society desires to express its deep sense of loss over the demise of its esteemed colleague, Dr. Robert A. Murray, which took place on February 27 last. Dr. Murray had been an enthusiastic member of the society nineteen years. It was his pleasure and pride to be with us, almost without exception, at every meeting.

He was a contributor to scientific medicine; and stimulated literary effort in general and special surgery, and was also a comrade and colleague in all the features which have endeared this Society to its members. His career as an interne in Bellevue Hospital in 1874 and 1875 under Alonzo Clark, James R. Wood, Alfred L. Loomis, Charles A. Budd, Abraham Jacobi, and others; his early professional association with Walter R. Gillette; and his rapidly growing medical practice gave to his membership qualities of a high order; while his happy disposition, his fund of humor, and his youthful geniality have left an indelible impress on all his surviving colleagues of the Society, never to be forgotten.

We desire to inscribe these admirable gifts of attainment and of personality upon the records of this Society and to convey our high appreciation of this esteemed colleague to the members of his family. By your Committee, Edward S. Peck, Henry Ling Taylor.

Obituary Notes.—Dr. Levi Farrow of Hackettstown, N. J., died at his home on March 21, of disease of the kidney, aged 64 years. Dr. Farrow was graduated from the College of Physicians and Surgeons, New York, in 1865.

Dr. Cyril Fulton of Lyons, N. Y., died at his home of pneumonia, on March 22, aged 40 years. Dr. Fulton, who was of Canadian birth and a direct descendant of Robert Fulton, was graduated from McGill University, Medical Department, Montreal, in 1892, and began his practice in New York State in 1895. He was a licentiate of the Royal College of Physicians and Surgeons of Canada, a fellow of the Rochester Academy of Medicine, and a member of the American Medical Association and the Central New York Medical Society.

Dr. Robert Reyburn of Washington, D. C., died at his home on March 25, at the age of 75 years. Dr. Reyburn was graduated from the Philadelphia College of Medicine in 1856, and practised medicine in Philadelphia until 1862, when he entered the United States Army as a surgeon. After his retirement in 1867, he resumed his practice in Washington, and in 1881 was one of the physicians in attendance upon President Garfield after he was shot. He was for some years dean and professor of hygiene and preventive medicine in the medical department of Howard University, and was a member of many scientific societies, and an honorary member of the Société française d'electrothérapie of Paris. He had written a clinical history of the case of President Garfield, as well as many contributions to medical journals.

Dr. Simeon O. Pilling of Hartford, Conn., died at his home on March 17, aged 44 years. Dr. Pilling was a graduate of the medical department of Boston University and served as surgical interne in the Massachusetts Homeopathic Hospital. He had practised in Newburyport, Mass., until his retirement, because of failing health, a short time ago.

Dr. Freeman E. Small of Portland, Me., died in the Maine General Hospital on March 19, aged 54 years. Dr. Small was graduated from Amherst in 1877, and from the Maine Medical School in 1879.

He was a member of the Maine Medical Association, the Cumberland County Association, the Portland Medical Society, and the American Public Health Association.

Dr. JOHN LAWRENCE CLEARY of Kenosha, Wis., died at his home of cancer of the face on March 12, aged 62 years. He was graduated from Pulte Medical College, Cincinnati, in 1878; was a veteran of the Civil War, a member of the State Medical Society, and a charter member of the Kenosha County Medical Society, and was for two terms a member of the Wisconsin State Board of Control.

Dr. THOMAS STERLING BARCLAY of Detroit, Mich., died at his home on March 14, aged 67 years. Dr. Barclay was born in Scotland, and received his education in Glasgow, graduating from the College of Physicians and Surgeons in 1865. In 1867 he removed to Canada, and in 1875 to Detroit, where he had since practised.

Dr. GEORGE A. BIDDLE of Emporia, Kan., died on March 13 of kidney disease, in the 63d year of his age. Dr. Biddle was graduated from the Bellevue Hospital Medical College in 1869, and was one of the oldest physicians in Emporia. He was a veteran of the Civil War, having served in the First Indiana Heavy Artillery.

Dr. F. A. A. BELINGE of San Francisco, Cal., died in the Lane Hospital on March 14, after a long illness. He was graduated from the Cooper Medical College, San Francisco, in 1870, and was a former president of the San Francisco Medico-Chirurgical Society of San Francisco, and a member of the commission on insanity.

Dr. TAPPAN E. FRANCIS of Brookline, Mass., died at his home on March 20. Dr. Francis was born on August 28, 1823, and was graduated from Harvard University in 1844, and from the medical school in 1847. He had practised in Brookline from 1850 until his retirement in 1893. He was a member of the Brookline school committee and trustee of the Brookline public library for many years.

Dr. FERDINAND C. HOTZ of Chicago, Ill., died on March 21 of pneumonia, aged 65 years. Dr. Hotz was born in Germany, and was graduated from the University of Heidelberg in 1865. In 1868 he served as assistant surgeon in Knapp's eye clinic in Heidelberg, and the following year removed to the United States, settling in Chicago, where he became wirely known as an ophthalmologist. He had been surgeon to the Illinois Charitable Eye and Ear Infirmary since 1876, professor of ophthalmology in the Chicago Polyclinic since 1888, and professor of ophthalmology and otology in the Rush Medical College since 1898. He was a member of the American Medical Association, one of the founders and a former president of the Chicago Ophthalmological Society, and a director of the Chicago public library. He had made many contributions to medical literature on ophthalmological subjects.

Dr. THOMAS J. BEATTY died at Philadelphia on March 22 at the age of 48 years. He was graduated from Jefferson Medical College in the class of 1880. He had been a medical inspector of the Bureau of Health, and for some years assistant chief medical inspector.

Dr. J. ORLANDO WHITE died of angina pectoris at Camden, N. J., on March 23 at the age of 62 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1868. He was at one time president of the Camden County Medical Society.

Obituary.

PHINEAS SANBORN CONNER, M.D., LL.D.

CINCINNATI.

DR. P. S. CONNER, who died of apoplexy at his home in Cincinnati on Friday of last week, was for many years one of the leading surgeons of the Ohio Valley. He was born in West Chester, Pa., August 2, 1829, and was graduated in arts from Dartmouth College in 1859. He then studied medicine in Philadelphia, being graduated from the Jefferson Medical College in 1861. Immediately upon graduation he entered the medical corps of the army as assistant surgeon, and served throughout the Civil War, being retired in 1866 with the brevet rank of major. He then began practice in Cincinnati. He was for forty years professor of surgery in the Medical College of Ohio and for more than half that period held the same chair in the Dartmouth Medical College, his lectures being delivered there during the summer. In 1884 his Alma Mater showed her appreciation of his loyal service by conferring upon him the honorary degree of Doctor of Laws. A few days before his death Dr. Conner delivered a memorial address at the Cincinnati Academy of Medicine on the life and works of the late Dr. Reamy, his contemporary and colleague for many years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

TUBERCULOSIS; WASHINGTON CONGRESS, BRITISH DELEGATES REPORT—TROPICAL DISEASES; A BLUE-BOOK, INDIAN BRONCHITIS AND SPIROCHETES, YELLOW FEVER—THE KING'S FUND—DR. WELIAMINOFF, F.R.C.S. (LON.)—OBITUARY.

LONDON, March 12, 1909.

A WHITE paper has been issued containing the report of the British delegates to the International Congress on Tuberculosis, held at Washington last autumn. Of course, you know all about the debates and the information furnished respecting the methods of prevention and so on adopted in your country. You may nevertheless like to learn something of the impression produced on our delegates and their conclusions. They express satisfaction that on so momentous a subject there was practical unanimity of scientific opinion and administrative aspirations, giving a prospect of a rapid extension of preventive measures and a more rapid decline in the mortality. They also find it satisfactory that objections to compulsory notification are rapidly disappearing. Sanitary authorities are thereby enabled to carry out precautionary measures, and patients obtain valuable official and private help, which, without notification, would have been absent, deficient, or belated. Thus the patient will learn how to protect himself from reinfection and his family and fellow workers from infection. The delegates regard compulsory notification as an indispensable step toward the suppression of the disease. They were greatly struck with the extent to which private and public agencies for the prevention of tuberculosis have been successfully coordinated in America and Germany, and they think there is much that is interesting in the cooperation shown, although the principle is not unknown here, but has to some extent been tried in London and other cities. Our delegates seem to have been much pleased with your day and night camps as valuable auxiliaries to hospitals and sanatoria. The chief aim of "the day camps," they say, is educational, though the patients there treated by day and who return to the

city at night commonly show improvement. The night camps" provide for consumptives who are able to work and cannot afford to give it up. After the day's work, instead of going to crowded homes, they pass to the night camps, where the conditions are favorable. They also learn to avoid risk to others. This educational result is of great economic value to the wage earner individually, as well as to the community. This is of the highest importance, considering the protracted course of the disease. The more this knowledge is diffused the more readily will precautions be taken. Educational agencies are largely employed in the United States, and of them the delegates think "traveling tuberculosis exhibits" most popular. They mention that of the Boston association as excellent, with its maps, charts, models of tents and buildings, consumption-breeding tenements, and inexpensive housing conditions recommended. Also the set of 200 slides which has been set up in fifteen cities and seen by 92,000 persons during the present year.

You will naturally suppose that conclusions arrived at with such unanimity will be enforced as far as practicable in the countries represented. Here it may be said that our sanitary authorities are prepared to carry them out, and indeed they have been largely anticipated. The Local Government Board's medical officer has now issued a brief memorandum, which is mostly a supplement to the circular issued last year to Boards of Guardians and other sanitary authorities. In it the conclusions of the congress are pretty fully adopted. Thus the education of the consumptives and their families as to the nature and prevention of tuberculosis is insisted on. Special instruction of friendly societies, trade unions, and other circles is suggested, as well as the Army and Navy. To place the patients in healthful surroundings is more important than drug treatment, and so the dispensary and sanatorium are commended and the best results are to be secured by "active cooperation between voluntary and official workers and agencies"—an echo, this, of the Washington congress, as also is the reference to the "long duration and occasional long latency of the disease," which must entail a continuous effort to suppress its ravages. Dr. Newsholme, however, is optimistic and thinks that "administrative measures will enable sanitary authorities gradually to bring tuberculosis within their control, and to secure that it will become as much a disease of the past in this country as leprosy has become."

A bluebook has been issued containing the report for 1908 of the Advisory Committee for the Tropical Diseases Research Fund, which included contributions from the Imperial Government and various colonies. A grant of £1,333 was made to the London school, £1,000 to that of Liverpool, £750 to the London University as stipend for a professor of protozoology, £100 to Cambridge University for a research studentship in medical entomology, and £400 to the Australian Institute of Tropical Medicine. The volume gives an account of various measures taken against malaria, all of which have been attended with success. Those aimed at the destruction of mosquitos and their breeding places are of the greatest importance, though where this has not been accomplished prevention of access to rooms and houses by wire gauze, etc., must be enforced.

The Society of Tropical Medicine is naturally closely associated with the school, though not identical with it. In the society many men of great experience in the tropics foregather and the proceedings are of wide interest. Last month there was a paper on a form of bronchitis in India which Dr. H. G. Waters found associated with a species of spirochete. At first thought one might feel doubtful whether the spirochetes were pathological and Dr. Waters himself did not at first attach importance to their presence and only accepted the conclusion after careful consideration. His first case was admitted with a temperature of 104°, a cough, with copious expectorations of mucus, and a few rhonchi. No tubercle bacilli or bacteria were found in the sputum, but many spirochetes. Temperature remained high, 102° to 104.5°, for three days, no oral sepsis or other local condition to account for it. In four days it fell to normal and the organisms disappeared, but fourteen days later a relapse occurred and they reappeared in enormous quantities. In the next few days Dr. Waters saw seven more cases in the same district and thought this suggested a specific infection. Dr. C. W. Daniels thought the fact of a series of cases with a definite type of illness was certainly suggestive, but apart from that skepticism would be natural, as one sees spirochetes in so many nonpathogenic discharges and exudates that it might seem possible the organisms were parasites of enlarged and unhealthy bronchi.

Dr. Low was in accord with the previous speaker and remarked that the spirochetes could not be reproduced in cultures, which made it difficult to prove pathogenicity. He asked if pneumococci had been looked for, to which Dr. Waters replied affirmatively.

At the same meeting yellow fever was under discussion. Dr. Faussett MacDonald, in some notes on Barbados, remarked that the island was commonly reported to be exceptionally healthy and it was a question whether yellow fever had ever been met there. Medical opinion was divided about it, some cases being diagnosed differently by the local practitioners. He held a certain group to be pellagra and was supported by Dr. Low, who commented on the exceeding difficulties of the diagnosis of yellow fever.

Then followed a paper on this disease, which every one admitted to be as important as it was interesting. This was by Dr. E. Ribas, Director of the Sanitary Department of San Paulo, Brazil, who said that extensive experiments at San Paulo completely established the accuracy of the American investigators in Cuba. There was no longer room for doubt, he said, that the disease was propagated by *Stegomyia fasciata*, and in all probability by that only. Fomites and other previously suspected agencies have no influence. When San Paulo was quite free from yellow fever he obtained some larvæ and sent them to a city where it was raging. The mosquitos hatched from them were allowed to suck a patient seriously ill and then brought back to San Paulo (360 miles), where they bit him and five other healthy volunteers. Three of these six persons had the fever. The other three escaped. These latter were himself and two other doctors who had worked with him in epidemics and so probably were immune. Dr. Ribas added that every epidemic had been stamped out by the extermination of mosquitos, together with general sanitary measures.

Dr. London Strain said he could personally confirm every statement in the paper. Since the campaign on the lines laid down by Dr. Ribas the cities of Brazil where the mortality was appalling had become prosperous.

Dr. Daniels admitted the *Stegomyia* had great influence, but remarked that yellow fever might disappear when the susceptible population was exhausted, and it had been observed to return at periods of about thirteen years, as in British Guiana.

Dr. Harford asked why Dr. Ribas classed as immune some inhabitants of the city who had not had the disease.

Sir Patrick Manson pronounced the facts in the paper of great value. One peculiarity of yellow fever, he said, was the immunity of the Creole. We know that natives in the tropics are immune to malaria, but that is because they suffered in childhood. Might that be the case with yellow fever? If so, we must consider it endemic.

Dr. Ribas, in reply, said immigrants arriving at Santos during an epidemic were hurried through the port. A stay of four or five hours sufficed for infection. It might be that mosquitos bit natives less freely than newcomers. But these natives had no immunity from other diseases. Cholera was even more fatal to blacks than to European residents in Brazil.

The annual meeting of the King's Hospital Fund was held on Wednesday, when the Prince of Wales, as president, took the chair and made a speech on the subjects mentioned in the report. He remarked that the Act of Incorporation, passed last year, had worked most satisfactorily and smoothly. He felt sure the amalgamation of the Hampstead and Northwest London hospitals would be approved by the charitable public and thought it satisfactory that the building of the combined Orthopedic Hospital will be ready for occupation this year. The committee of inquiry it was intended to appoint on the out-patient system, he decided, upon the advice of the executive committee, to defer until next year, as it will be some time before the evidence on which the report of the Poor Law Commission is based can be issued.

Lord Rothschild, as honorary treasurer, presented the accounts and explained the effect of the Act, which had been carried out successfully respecting the separation of the money into trust and nontrust funds. The former show an increased value of only £1,000, but the latter of £100,000. Since the inauguration of the fund the amount spent on administration, the re-

port shows, has been £1 4s. 8d. per cent. of the total amount received. This seems to me quite enough, considering that nearly all the officers are honorary.

Yesterday Dr. Nicholas Weliaminoff, Privy Councilor of State and Professor of Surgery in the St. Petersburg Academy of Medicine, attended the council meeting of the Royal College of Surgeons and signed the roll. In 1900 he was elected an honorary Fellow, but had been unable to come to England until now, when he is in attendance on the Empress Marie Fédorovna during her visit.

At the same meeting the report of the committee for preparing a new by-law on the admission of women was received and will be further considered at the next meeting. A committee was appointed to consider the bearing on the rights of Fellows and Members of the British Medical Association's petition for a charter.

Mr. Thos. Wakley, editor of the *Lancet*, died on the 5th inst., aged 57. He was the grandson of the founder of the journal, the late Thos. Wakley, M.P., who had two sons, both of whom worked on the paper, and the only son of one of them, Thos. Henry Wakley, F.R.C.S. The late editor had been ill for the last two months. He was educated at Westminster School and Trinity College, Cambridge. Afterward his medical curriculum was fulfilled at St. Thomas's Hospital.

Captain Frederick Hallam Hardy, R.A.M.C., died at Aden on the 8th inst. of sleeping sickness, aged 36. He was on his way home from Nyassaland. He entered the service in 1900 and was appointed Medical Officer in the Central African Protectorate.

OUR PARIS LETTER.

(From Our Regular Correspondent.)

USE OF ARSENICAL COMPOUNDS IN AGRICULTURE—TREATMENT OF FRACTURES BY OPERATIVE REDUCTION WITHOUT FIXATION—TREATMENT OF WOUNDS OF THE CHEST—PREOPERATIVE STERILIZATION BY HOT AIR OF HOLLOW ORGANS SUBJECT TO SEPTICEMIA—SEVERE INTOXICATION WITH NITRATE OF BISMUTH.

PARIS, February 27, 1909.

THE officers of the Academy of Medicine for the year 1909 include for president Dr. Leon Labbé and for vice-president Professor Dieulafoy. A most interesting discussion arose on the employment of arsenical compounds in agriculture. Mr. Charles Monreu, who wrote upon this interesting question, showed how many questions were brought up by the use of arsenic in agriculture. Arsenical compounds are most advantageous for killing insects; they are at the same time powerful insecticides and economical ones, and from an agricultural point of view are an excellent means of defense; unfortunately, their use presents great dangers for the cultivator of the fields, whose life is passed in the midst of an atmosphere of arsenic, and for the consumer constantly exposed to the danger of eating poisoned produce. Each of these classes courts death daily. Therefore, a commission appointed by the Academy of Medicine, having balanced these advantages and disadvantages of the agricultural use of arsenic, has unanimously voted for the prohibition in a radical and absolute manner of the use of arsenic in agriculture. It demands the prohibition of the sale and of the use of arsenic and of its compounds for the destruction of insects.

Monsieur Linossier noted a distinction among the compounds of arsenic. He proposed the prohibition of the use of soluble compounds of arsenic and of arseniate of lead, with tolerance and strict regulation of the use of arsenites and of the arsenate of copper.

Monsieur Armand Gautier, considering that the object of the Academy is above all the defense of the public health, demanded of the Academy that it support the conclusions of the commission, and not allow itself to be influenced by the interests of agriculture alone, however important they may be, since they should be secondary to the interests of the health of the whole people, of which the Academy is the authorized defender. Hanriot and Cazeneuve were partisans of the complete prohibition of the use of arsenic. Weiss, on the contrary, was absolutely opposed to the prohibition of arsenical compounds in agriculture. He believed that we do not find documentary proofs of the danger of manipulation or arsenical compounds. He considered that the prohibition of arsenical compounds would be deplorable, and would make more difficult the position of the agricultural population, by taking away from them the means which are recognized as the most effective insecticides. Consequently he demanded that the Academy decide on further investigation before giving a decision.

Finally, the Academy, in view of the importance of the interests at stake, and thinking that it had not examined sufficiently into the nature, frequency, and gravity of accidents resulting from the use of arsenical products in agriculture, decided that a medical investigation of the subject was in order.

The president of the Society of Surgery, for 1909, is Reynier, its vice-president Routier, and its secretary Broca. An interesting discussion has arisen as to the treatment of fractures by operative reduction without fixation. Willems of Gand is a partisan of reduction of fractures by operation, but only when they are irreducible. He practises reduction after opening the site of fracture by incision, disengages the fragments, puts them in coaptation, and then, instead of fixation by mechanical means, he applies simply an apparatus to maintain the reduction. Walther supported the conclusions of Willems, and is completely of his opinion. Demoulin recalled that the rules for the treatment of fractures mentioned by Willems were long ago brought forward by Hennequin, who applied his apparatus after reduction of fractures with or without operation, and then utilized continuous extension. Thierry believed that when the location of a fracture has been incised it should not be treated by a simple apparatus for keeping the fracture in position. He thought that a mechanical means of keeping the fragments in position, preferably a ligature, is necessary, and for that ligature he makes use of copper or bronze wires. Quénu believes that to accept the operative treatment of simple fractures is not desirable in all cases. In fractures sutures can generally be dispensed with, but in some cases suture is very useful; well placed and with perfect asepsis a bony suture has not the inconveniences attributed to it.

Auvray gave an interesting communication on the treatment of wounds of the chest. This author is in general a partisan of abstinence from surgery in the treatment of wounds of the chest. In such cases medical treatment is generally sufficient to obtain a cure. Still there are cases in which the surgeon must interfere, and the difficulty is exactly to seize the moment in which operation becomes necessary. As to the method of opening the thorax, Auvray believes that resection on one side, for a length of 10 centimeters, is generally sufficient. He insists on the necessity of a systematic search for the pulmonary orifice of exit for the projectile on the posterior surface of the lung, and the posterior half of the internal surface. The exploration of the posterior surface of the lung should be as far as possible a visual one; when this is impossible the finger should be used. Since the wound becomes infected very easily, Auvray thinks that it is best to make at once a counter opening in the pleura at the lowest point. Souligneux believes that wounds of the chest, since they are accompanied by hemorrhage into the pleural cavity (hemothorax), are almost always curable without operation when the hemorrhage is not very abundant, which is generally the case. But in severe cases it is very difficult to know whether to interfere or not. Souligneux believes that whenever this question comes up it should be answered in the affirmative. We must not have recourse to "armed expectancy," a word behind which the surgeon intrenches himself when he allows his patient to die. Rapid intervention is necessary, unaffected by theoretical questions. A large opening of the thorax, such as to permit the collapse of the lung, contributes to the arrest of hemorrhage. We may, then, conclude that in wounds of the chest accompanied by severe hemorrhage operation is better than conservatism. It is better to do an exploratory thoracotomy, which may be enlarged in case of necessity, should a suture of the lung become necessary. In case of hesitation it is always better to operate.

Quénu made an interesting communication on the preoperative sterilization of hollow organs with septic contents by means of hot air. Surgeons who have operated on hollow organs with septic contents, and especially cancers of the uterus and rectum, have been cognizant of grave dangers to the patient operated upon from the presence of the smallest amount of effusion from the contents of the cavity. The means employed up to the present time have been insufficient. Quénu thinks it possible to solve the problem by sterilizing by means of hot air not only the liquid in the cavity, but the walls themselves of the hollow organ. This method he employed lately in a woman having cancer of the uterus. Before proceeding to the extirpation Quénu blew into the cavity of the uterus hot air at 600 degrees. Then he went on to enucleate the uterus by way of the abdomen. This patient recovered perfectly without any complications. After the removal of the uterus bacterial cultures were made from the cor

tents of the uterine cavity and the inoculated tubes remained perfectly sterile.

The officers of the Medical Society of the Hospitals include as president for 1909 Oulment, succeeding Chauffard, president for the preceding year, and for vice-president De Bourmann. Bensuade and Agasse-Lafont made an interesting communication on grave intoxication with subnitrate of bismuth. These authors have seen 15 cases of this intoxication. The symptoms accompanying these intoxications are almost always the same; the attack is very sudden, and begins a few hours after the injection of the bismuth. It is characterized by vertigo, nausea, convulsions, tachycardia, dyspnea, hypothermia, and above all, excessive cyanosis. The evolution is very rapid; generally the case ends in recovery, but at other times the patient dies in convulsions or coma. Of 15 cases four were fatal. The intoxication in these cases is probably due to the production and absorption of the nitrites. The gravity of this accident leads to the question whether the employment of subnitrate of bismuth should not be limited. We know that the injection of subnitrate of bismuth permits of interesting radiological results, and the appearance and frequency of these intoxications with bismuth coincide with the discovery and extension of radiology. It would appear better to replace the subnitrate of bismuth in radiology by carbonate of bismuth, which is much less toxic. In therapeutics we may continue to utilize the marvelous analgesic properties of subnitrate of bismuth without ever giving more than 20 grams per day.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 18, 1909.

Arteriosclerosis.—After a general enumeration of the causes and symptoms of this condition and brief references to two personal cases, George S. C. Badger says that the presence of arteriosclerosis does not always call for treatment, as there may be no symptoms attributed to it, while whatever damages may have been wrought in the vessel walls cannot be cured. But the process may be stayed or at least hindered, and we must begin by cutting out the etiological factor, be it immoderate drinking, overeating, dissipation, or excessive muscular efforts. As to blood pressure, a high pressure may be in some instances a protection against disaster. A falling pressure is an ominous sign. If high pressure causes symptoms we can reduce it by the rapidly acting drugs, such as nitroglycerin, nitrites, aconite, erythrol, tetranitrate, etc., Occasionally vivisection is called for. The iodides are useful but must be long continued. They lower the pressure possibly by lessening the viscosity of the blood. Occasionally vertigo is a prominent symptom and defies all treatment. Above all, the manner of living of the patient must be carefully regulated.

Some New Applications of Electricity and Light in Medicine.—H. W. Van Allen reviews some of the latest applications of these agents, calling attention to the use of the *x*-ray in detecting stones in the urinary tract and in giving a good idea of the position and character of the kidney in the majority of cases. Tuberculous kidney has a characteristic shadow, while cysts, abscesses, and tumors may be detected. Movable kidney, if out of position, may be detected. A new instrument, called the statin, consists of a box lined with *x*-ray light-proof material with an adjustable window and by means of its use fluoroscopic work hitherto dangerous to the operator can be carried out without any harm. All the movable organs can be studied at one's leisure, *e.g.* the heart, lungs, etc. The outline of hollow organs may be made out by the introduction of oxychloride of bismuth, which is opaque to the *x*-ray, and in the same manner also the state of the entire gastrointestinal canal and of the peristaltic mechanism can be traced. The course of old sinuses may be traced by injection with warmed mixtures of bismuth and vaselin. The high-frequency, high-tension current has proven of great value in chronic inflammatory conditions of the joints, muscles, and veins. A modern plan of using electricity is that of autocondensation, in which the actual current does not enter the patient, but is in his immediate neighborhood, and he is charged by induction. It is claimed that in this way the arterial tension is reduced. Light combined with heat is useful in superficial skin conditions, and in local inflammation of bones and joints.

New York Medical Journal, March 20, 1909.

Angina Pectoris and Overfeeding.—Judson Daland reports one case at length, noting the point of interest that the usual causes such as nicotine, alcohol, syphilis, and excessive muscular exertion were all wanting. The changes in the walls of the radial arteries are less than would be expected at the patient's age, 66 years, while the amount of obesity was but moderate. The man, a lawyer, had been accustomed to mental overexertion and the excitement of legal business for many years, and in young manhood had had rheumatism. In addition he was in the habit of bolting large quantities of food rich in proteids and carbohydrates, which caused much metabolic disturbance as indicated by indicanuria, acetonuria, and glycosuria. Regulation of his diet caused a cessation of symptoms for five years, but they reappeared on his relaxation of his prescribed manner of living. It was judged that he had dilatation of both sides of the heart with degeneration of the myocardium. Disease of the coronary arteries is but one of many causes leading up to angina pectoris, but advanced coronary and myocardial changes may coexist without anginoid attacks. Chronic nicotinism generally causes attacks of pseudoangina. The author calls attention to the importance of using bending movements (described in his paper) to determine the reaction and contractile power of the myocardium.

The Excision of Chancre.—G. F. Lydston thinks that the claims of the supporters of the theory that the *Spirochæta pallida* is the essential germ of syphilis have been rather overstated, but he is willing to admit that it is not far from fulfilling the requirements of specificity. Diagnosis must not be based on its presence alone. In regard to the excision of chancre, he calls attention to the caution necessary in deciding on the exact nature of the sore excised, because (1) even in untreated cases the observable symptoms may not develop for weeks, months, or even many years after the initial lesion; (2) no system of medication yet devised can be relied upon to altogether prevent secondary lesions, and (3) excision was tried long ago and found wanting in the prevention of secondary lesions. His own conclusions, based on thirty years' experience, are that excision does not prevent constitutional syphilis, though sometimes it seems to modify the subsequent course of the disease. He does not dare to omit medication in his own practice. To jump at the diagnosis of syphilis from the mere presence of the spirochetes is fallacious. Its presence is an imperative admonition not to cauterize in any way. The deep cauterization recommended by some authors is strongly condemned. The initial lesion should be healed as quickly as possible, as it is always a source of danger to others and there is always danger of a precocious, malignant, or at least a disfiguring syphilis.

Unusual Cases of Bromide Eruption in Children.—F. C. Knowles gives an elaborate exposition of this subject, and adds the histories of four personal cases. His summary is as follows: (1) Bromide eruption may occur in those who are susceptible, independent of the dose of the drug or of the length of administration. The larger the dose or the longer the ingestion, the greater is the chance of an outbreak; (2) in most cases there are practically no constitutional or subjective symptoms; (3) because of the slow elimination the eruption may continue for some weeks after the drug has been discontinued; (4) almost any type of eruption may be present in childhood; the lesions are usually larger and more persistent than in adult life. The extremities and the face are the parts most frequently attacked; the most extensive eruption occurs in the majority of cases on the legs. (5) Lesions have great tendency to occur at points of previous inflammations, such as on vaccination scars, injuries, etc.

Journal of the American Medical Association, March 20, 1909.

Gastrointestinal Disturbances of Arteriosclerosis.—J. J. Gilbride calls attention to the disorders of the digestive tract due to general or localized arteriosclerosis. Within a few months he has treated ten cases of this class, several of which he reports in this paper. The patients are usually over 40 years of age. The symptoms are generally, first, abdominal pain, paroxysmal in the beginning, later becoming continuous, and next to this in frequency is weakness and sometimes loss of weight, the latter being due, in part, to the dieting for the dyspeptic symptoms. Abdominal distention and belching are often present and the association of dyspeptic symptoms with weakness and loss of weight may cause suspicions of malignant gastric disease. The appetite may be normal, increased or decreased, the bowels are variable, the urine is frequently lessened in amount and some patients suffer from vertigo and a few from visual disturbance. It is important to determine the blood pressure, and to some extent this can be estimated by the amount of pressure

necessary to arrest the pulse in the radial. It is advisable also to analyze the gastric contents. The treatment in the cases reported is given as ten drops of tincture of strophanthus three times a day and theobromin sodium salicylate, five grains, three times a day. In one case dilute hydrochloric acid, ten drops three times a day, was also given. An analysis of the conditions in the various cases is given as follows: "The conditions of gastric functions in four of those cases were: Motility increased in three; free hydrochloric acid, a trace in one and absent in two, normal in one; absence of lactic acid in all four, and no Oppler-Boas bacilli found. Peptic digestion was not determined in those cases, but I made an analysis in one other case recently and found peptic digestion to be normal, although hydrochloric acid was absent. In one patient (Case 3) no gastric analysis was made. Weakness and loss of weight are prominent symptoms in some cases. The abdominal aorta was tender in all the cases. The association of pharyngitis in two cases is of interest, as its symptoms had been misleading. Gastroptosis or visceroptosis was present in only one case. In some cases nitroglycerin or the nitrites give relief when other remedies are of no benefit. All of the patients whose cases are reported had been dieted and drugged for dyspepsia without relief."

Neurofibromatosis.—W. Healy reviews the literature of this subject, noting especially the cases with intradural complications. It has been held by certain authorities that the condition is a congenital pathological one, and, though only five or six cases in which the tumors are both peripheral and intracranial have been reported, it has been suggested by Roux that perhaps neurofibromatosis is always both central and peripheral, and that the evolution from benign to malignant growths determines the symptomatology. On the other hand, however, we have reports of cases running a benign course with stationary intracranial symptoms. The symptoms are, of course, those of tumor of the brain in general, which are significant for diagnosis. First, there are often simultaneous, or almost so, involvements of nerves on both sides which preclude the assumption of a single unilateral or even mesial growth. Second, there are apt to be remissions of months' duration which are hard to explain. Death is frequently determined indirectly by involvement of the vagus, causing difficulty of swallowing, etc., and consequent aspiration pneumonia. Healy reports a case which exhibits the rare combination of symptoms of intracranial peripheral involvement and presented also other peculiar symptoms which embarrassed the diagnosis for a while. During four weeks under treatment in the hospital there was no change in the patient's condition, except an increase in the tachycardia, probably due to the vagus involvement. Treatment, here, as in other cases, was unavailing. He has found no record in the literature of operation for the brain tumors, nor could it be expected to succeed, considering the multiplicity of the growths. It was reported, however, in the Chicago Medical Society by Dr. Carl Wagner that the patient came later under his care and that an *x*-ray examination revealed a cerebellar growth, for which he operated and discovered a tumor. The patient did not rally, but succumbed to quickly developing respiratory difficulties, and unfortunately no autopsy was obtained. The case is, however, clearly enough one of the few recorded cases of peripheral plus intracranial neurofibromatosis.

Septal Deviations.—N. M. Black is convinced that not only are dental and jaw irregularities a decided factor in the production of deflected septa, but that complete relief without possibility of return of the condition, when found in conjunction with dental deformities, can be secured only by first correcting the deformity in the superior maxilla. He reviews at some length the literature of the opinions as regards the etiology of septal deviation and its connection with oral and dental irregularities, and says that it is unaccountable to him that while rhinologists practically acknowledge the important part played by irregularities in the upper maxilla in the production of septal deformities, they do not apply that knowledge in the treatment of the conditions. He finds nowhere in the directions for treatment any suggestion for the correction of these deformities. It is far better, in his opinion, to seek first to increase the size of the nasal fossæ before depending solely on the removal of superfluous tissue, however beneficial that may be as a later measure. This widening, so far as his knowledge extends, can only be accomplished by widening the arch of the superior maxilla. This procedure, to be effective in enlarging the base of the nares, must be essentially different from the ordinary expansion for the regulation of the teeth in abnormal position. Such expansion relieves the pressure on the septum, which tends to straighten itself, enlarging the breathing space, and reduces the static congestion, which further adds to the nasal capacity. The turbinates become reduced in size and adenoids rarely fail to become smaller after nasal breathing is established. Black credits the successful results so far in this line solely to Dr. G. V. I. Brown and, while he differs from him somewhat in their explanation, concedes that his theory is probably correct, viz., that it is entirely due to the separation of the median palatal suture. Black thinks that there is also a lowering of the vault, the result of an outward tilting of the alveoli, which pulls the septum down. As to the age when this should be done there is some dispute. Kyle holds that little can be done successfully in the way of widening the nasal space after the seventh year, and deformations of the septum may appear before that age. Gray, on the other hand, says that the intrapalatine sutures are not obliterated until middle life, and, this being the case, widening operations ought to be possible till then. The great reason why septic deformities tend to return is, in the first place, the difficulty of removing sufficient tissue to prevent backward pressure on the septum, and, in the second place, the main etiological factor—some dental or jaw irregularity —is overlooked and goes uncorrected.

Ataxic Arsenical Neuritis.—C. M. Byrnes reports a case of this disease which is of interest on account of its infrequency and also because of its pseudotabetic features and the symptom of loss of osseous sensibility which has been hitherto unreported in this form of neuritis, though common in other forms of neuritis and in tabes. The cause was attributed at first to exposure to fresh paint containing white lead used in house painting, but it was afterward ascertained that it was due to arsenic introduced into a can of baking powder, probably with criminal intent. The loss of the vibratory sense or osseous sensibility is specially noted as occurring in the ataxic form of neuritis. It illustrates a resemblance to tabes. In reviewing 200 cases of neuritis from various causes other than multiple neuritis he has not found one case in which this symptom was present.

Uterine Fibroids and Malignant Disease.—Ellice McDonald has collected and tabulated, as regards the incidence of occurrence of malignancy, 700 cases of uterine fibroids. The tables show that adenocarcinoma of the fundus occurred in 20, or 2.9 per cent.; squamous carcinoma of the cervix in 6, or 0.8 per cent.; sarcoma in 7, or 1 per cent., and chorioepithelioma in 2, or 0.3 per cent.; the total number in the whole 700 being 35, or 5 per cent. The relative frequency of adenocarcinoma is thus seen to be much greater with fibroids than that of squamous carcinoma and the author does not accept an etiological relation between this latter form and fibromyomata, but considers them accidental. While a common etiological factor may partly explain the association of adenocarcinoma and fibroid tumors, it is probable that the fibroid has some part in causing this association. The tendency of pathologists has been to doubt the possibility of a sarcoma arising from a uterine myoma, but most now admit its occurrence. It is the form of malignancy most likely to be overlooked, as shown by Winter's figures, and that author estimates that systematic search would reveal sarcoma in about 4 per cent. of these growths. This is not borne out by McDonald's tables, in which microscopic examination was made in all cases. The two cases of chorioepithelioma malignum are supposed to be the only ones so far reported of this form as a complication of fibroids, and are of interest chiefly on account of their rarity. In the whole number of malignant growths there was only one, a squamous carcinoma, occurring in a patient under forty, and their frequency increased with each decade after that, being 5 per cent. in the fifth, 12.7 per cent. in the sixth, and 23.8 per cent. in the seventh. In view of this large percentage of occurrence of fatal disease among patients with fibroid tumors, and the great increase of such complications after the age of 40, it seems wise for a physician to advise the removal of such growths after that age. The probabilities are that malignant change will occur in one case in 20 between 30 and 40, in one in every 8 between 50 and 60, and in every 4 between 60 and 70. Were there any certain way of determining the advent of malignancy the danger might be less, but who can say how soon any fibroid may undergo this change? The smoldering fire should not merely be watched until the house is in flames.

The Lancet, March 13, 1909.

Tabes Dorsalis with Unilateral Anesthesia; a Contribution to the Pathogenesis of the Disease.—The illustrated paper of H. T. Thompson opens with a discussion of the current theories as to the pathology of tabes and

then considers the nature of the sensory changes in the disease. He says that these changes are not due to changes in the peripheral nerves, nor to a coarse lesion of the posterior roots. On comparing these changes with those due to lesions of the secondary sensory system, the similarity between them is noticeable. The separation of painful from thermal sensibility, the disassociation of the sense of passive positive from tactile sensibility are found both in tabes and in intramedullary lesions from various causes. The separation of the pain of deep pressure from the recognition of the pressure itself and its association with the loss of cutaneous pain are characteristic of both tabes and the lesions of secondary sensory neurons. Consequently we must conclude that in tabes the sensory loss is similar in character to that met with in lesions of the secondary sensory system. In tabes the primary sensory neurons are alone affected. The primary change in the disease begins in the synaptic junctions, between the primary and secondary neurons. Hence tabetic lesions must be considered as a degeneration of the pericellular network around the cells of the secondary sensory neurons. The lesion at the synaptic junctions above referred to explains how it is possible that the various tactile and painful, thermal, etc., sensations may be affected, alone or in conjunction. A gradual affection of the first synaptic junction would explain the characteristic delay in response to stimulation, which is more often present in tabes than in any other sensory affection. The author does not believe that meningeal thickening around the posterior nerve roots is a causal factor in tabes. The initial lesion rather lies within the cord itself. The paper concludes with an interesting history of the case of a woman of 51 years, in whom the anesthesia was unilateral, so that a comparison with normal sensibility could be accurately made. In addition, the psychophysical examinations were made under favorable conditions, and as the patient died shortly after from heart failure, due to syphilitic mesaortitis, it was possible to examine the cord. Full pathological findings are given.

Hydrochloric Acid in the Gastric Contents of Cancer.—The paper of S. M. Copeman and H. W. Hake is a reply to criticisms of B. Moore on a previous contribution of the joint authors, and must be read by those interested in the argument. It does not lend itself to abstracting.

Medical Ionization: Its Uses and Possibilities.—After explaining ionization, its method of application, and the tissue changes which it causes, N. S. Finzi says that ions may be used for general or local effects or for both. The general effects are about the same as those following the internal administration of the various drugs, but ionized drugs act more slowly and continue acting much longer, owing to their being only gradually disengaged from the combination which they form in the tissues into which they are driven. For purely general effects oral administration of the drug ionized as much as possible by being dissolved in a large quantity of water will, on account of its duplicity, be generally used. Many ions used for local medication pass into the system and exert constitutional effects. Purely local therapy may be directed toward the skin or the deeper parts, such as joints, muscles, and tendons. Another local use is to extract ions from the tissues, *e.g.* uric acid ions in gout. The author describes the simple galvanic apparatus required and its methods of application. He enumerates the various remedies used in this way and the lesions to which the method is applicable.

British Medical Journal, March 13, 1909.

A Case in Which Enterospasm Was a Pronounced Feature, Necessitating Abdominal Section Four Times Within Ten Months.—C. W. Dean refers to a case previously reported by a colleague under the title, "The Reality of Enterospasm and Its Mimicry of Appendicitis," and then gives notes of the case of his own patient, who was a woman of 28 years. Laparotomy was performed four times in less than ten months, a cyst of the ovary was removed at one operation; enterotomy at another; four inches of small gut removed at a third, and seven inches at a fourth. The ultimate result was that the patient is now in excellent health and feels perfectly well. The symptoms in all the attacks were those of acute abdominal pain and intestinal obstruction and were in each case urgent. At the final operation a loop of small gut was found tightly strangulated by an adhesion which had formed after one of the previous operations, and had become slightly gangrenous. In the author's view enterospasm accounts for many of those instances in which the acute symptoms simulate gastric ulcer or obstruction, symptoms perhaps not classical, but of such urgency as to allow of no delay, but in which nothing has been found on abdominal section to justify operation.

Diagnosis and Treatment of Chronic Ulcer of the Stomach and Duodenum.—Alexis Thompson analyzes 50 personal cases, in which the existence of ulcer was demonstrated on operation. The ulcer was in the pyloric ring, or antrum in 16, on the lesser curvature in 12, and in the first part of the duodenum in 17. In the remaining 5 there was more than one ulcer, one being in the duodenum in all of them. Thirty were in males and 20 in females. Age ranged from 21 to 67 years. The average for the onset of gastic ulcer was 32 years and for duodenal ulcer 38 years. In 3 there was no pain, in 3 little or no pain (all these involved the duodenum); in 8, more or less constant pain. In 4, there was an hour-glass contraction. In 10, pain was relieved by taking food. Tenderness over the epigastrium was present in 16, vomiting in 42, and hematemesis in 29, and in 11 there was also hemorrhage from the bowels. Constipation was almost universal and peristalsis was visible in 5. The author believes that in the majority of instances a differential diagnosis is possible between the two localities referred to in the title. He says that the chronic ulcer can be cured only by surgery and he advises operation because the ulcer will not get well otherwise, because the ulcer and its complications are the cause of considerable suffering and prevent the patient from working, and because the ulcer may become dangerous to life through starvation, hemorrhage, perforation, and transformation into cancer. The choice of operation lies between resection and gastroenterostomy. The author's operative results are as follows: Resection of stomach, 3 cases, with one death. Of the survivors, one well three years and three months later, one well two and a third years later, but with occasional pain and flatulence; gastroenterotomies, 47 with three operation deaths, two due to a bad vicious circle and one to septic peritonitis. Of the operation survivors, one was lost sight of, one died from each of the following: Exaphthalmogoitre, gastric cancer, urinary sepsis with enlarged prostate, and two from what their own doctors reported as acute enteritis. The remaining 38 patients are under regular observation, and all have done well.

Primary Diffuse Pneumococcic Peritonitis Treatment by Drainage and Pneumococcic Vaccine; Recovery.—H. B. Robinson's patient was a girl of 8 years with a tuberculous family history, who had a habit of holding her water for long periods. She was suddenly seized with abdominal symptoms suggestive of peritonitis with a boggy feeling for rectum on the right side and in Douglas's pouch. To the surgeon the condition suggested a perforative peritonitis due probably to a gangrenous appendix. The peritonitis was found to be typical, but the appendix was normal. For forty-eight hours after the operation the course was uneventful, but then her temperature began to rise and two days later it was proved that the peritoneal effusion was a pure culture of the pneumococcus and the vaccine treatment was begun, with happy results. She left the hospital well in about six or seven weeks. The diagnosis of this special form of peritonitis can hardly be made without the aid of bacteriology.

Berliner klinische Wochenschrift, March 1 and 8, 1909.

Frequency of Tuberculosis at Autopsies.—Beitzke has carefully examined 1,100 bodies, 397 of them belonging to children under fifteen years of age and 703 to adults, for signs of active, latent, or cured tubercular infection. Of the children, 13.6 per cent. proved to be tubercular: if infants under one week, all of whom were free from the infection, are excluded, 27.3 per cent. of the others showed signs of the disease. The percentage of tuberculous children under one year is quite small; it increases with the increase of age, and between six and fifteen years almost two-thirds of the children proved to be affected. On the other hand, the mortality from tuberculosis among children diminished with age, the lesions in the older ones being mostly of local character and but rarely the cause of death. Of adults, 58.2 per cent. proved to be tuberculous, the greatest number falling between the ages of sixteen and thirty. Of all the bodies, with the exception of infants under seven days, 51.4 per cent. proved to be tuberculous, 16.9 per cent. dying of the infection. While these figures are very high, yet they do not justify the statement of Naegeli that every adult is or was tuberculous. One might say correctly, however, that of the bodies reaching the autopsy table in a large city the great majority show signs of tuberculous infection. Comparison with earlier figures shows that the mortality from tuberculosis in such cities as Berlin has greatly diminished in the last ten years. So far as the general population is concerned, it remains true, however, that about one-half of all men show signs of tubercular disease at some time of their lives

Resection of the Hip-Joint for Tuberculosis.—König says that early resection of the hip-joint for tuberculosis has lost its popularity since the introduction of various orthopedic measures of treating the disease. There remain, however, a number of cases in which operative treatment is to be preferred to immobilization; the mere ease with which orthopedic treatment may be applied should not serve as an excuse for persisting in such treatment in the presence of extensive destruction of bone, with the formation of abscesses and fistulæ. The aim of every resection about the hip-joint should be to remove the diseased tissues completely; the failure of old surgeons in treating the disease was often due to the failure of fulfilling this important indication. König has treated altogether 568 cases of tuberculosis of the hip, 457 of whom were treated in the conservative manner from the beginning, but in 173 operation had to be done at a later date. Of those treated to the end by conservative measures 114 recovered function enough to be able to go about without the help of crutches or canes. Of the 274 patients on whom early resection was performed 66 were cured; that is, were enabled to walk well and showed no fistulæ. In quite a number of cases the results were excellent, the patients being able to walk long distances without difficulty. The mortality was greater among those who underwent resection, but this is explained by the greater severity of the pathological process in such cases and by the dangers of the operation in itself. As compared with resection of the hip for non-tuberculous osteomyelitis, the prognosis in cases of tuberculosis is much more unfavorable. Yet the above results show that resection of tuberculous hips in well-selected cases is a perfectly justifiable and successful operation.

Münchener medizinische Wochenschrift, March 2 and 9, 1909.

Effects of Laparatomy Upon the Lungs and Heart.—Lichtenberg has carefully examined one hundred patients before and after laparotomy in reference to the condition of their lungs and heart. Thirty-five patients showed pulmonary complications as a result of the laparotomy, while thirty-eight others developed a bronchitis. Only twenty-seven remained without any pulmonary or bronchial disturbance after the operation. Blood pressure fell in all patients who were operated upon under general anesthesia, remaining below the usual height for several days; the use of local anesthesia usually led to a rise in blood pressure. Lichtenberg concludes that pulmonary complications are much more frequent after an operation than is usually thought; the frequent rise in temperature after aseptic surgical procedures is probably due to such complications in a great number of cases. The lungs begin to show signs of such complications within two or three days after the operation. This fact shows that post-operative pneumonia is not due to the anesthetic, but must be referred to other causes, such as embolism.

Salt in Diet.—Mendel says that in the past it was thought that salt was quite an indifferent part of the diet, taking no part in metabolism and simply serving to make up for the amount excreted by the kidneys. It has been now shown, on the other hand, that salt can produce an edema or anasarca in the presence of diseased kidneys; such edema may be made to disappear with the cutting off of the salt in the diet and be made to reappear again on addition of salt. Even with normal kidneys susceptible persons may show water retention on great increase of salt in their daily food. The primary event in this cycle is the retention of salt, which is followed by the retention of water in the tissues; in healthy organisms, however, such retention is soon followed by copious secretion of fluids from all secreting glands. This fact has been proved by giving large saline infusions in animals, and it may be utilized in treating such conditions as peritonitis or a toxemia arising from any source. Abundant infusions of saline should be practised so that the current of fluids from the tissues is much more rapid than usual; such infusions may in this way lead to rapid detoxication of the organism. Salt retention alone, however, does not lead to the transudation of fluids into the tissues; it is followed by edema only if the blood-vessels have been damaged by some toxin, and in acute nephritis, which is so often accompanied by edema, the usual etiological factor such as an acute infection gives rise to such damage. In chronic nephritis the albuminuria of long duration gives rise to insufficient nutrition of the vessel walls, and as soon as salt retention occurs water is taken up from the vessels by the tissues.

Psychoneuroses and Gastric Disturbances.—Fleiner says that even in the normal animal the interdependence of psychic and digestive functions is very important. In disease this relation is often the overwhelming factor in the production of symptoms and their nature. The pathological changes may be quite similar in a number of cases, all different in their symptomatology because of the difference in the psychical natures of the patients. Strong characters often endure the results of anatomical and functional changes in such a manner that the disease in them is really latent; asthenic individuals present a variety of symptoms differing almost with each individual patient. To help these patients one must remember that they are to be treated, not their disease. Digestive and reproductive functions and organs, with their disturbances, stand in such close relations to the psychic life of the patient because they are closely connected with the self-preservatoin of the individual and the continuation of the race, two elemental forces in an animal. The usual explanation of the etiological relations between digestive disturbances and neuroses, which depends upon the continuous irritation of the nervous system by stimuli from the digestive organs carried by vagas and sympathetic nerves, is true only in the minority of cases. The opposite is often true in so-called nervous disturbances of digestive function, the state and changes in the central nervous system being primarily responsible for the digestive neuroses. Fear, anguish, shock, psychic phenomena of most varied nature have an extremely important effect upon the motor, secretory and digestive functions of the stomach and intestines. Indeed, one can say that there are no primary nervous dyspepsias; instead, there exist only functional disturbances of gastric and intestinal functions of psychogenetic character. Once such diagnosis is assured, the treatment must be psychotherapeutic; medicines and other measures are only adjuvants. The frequency of such psychogenetic disturbances of the digestive function is shown by the fact that one-third of Fleiner's patients may be classed in this category.

Bacilli Carriers.—Liefmann says that the danger of chronic bacilli carriers has been somewhat overestimated. Statistical studies show that only 4.11 per cent. of typhoid fever cases are due to infection through such individuals. He had placed a number of bacilli carriers together in one large apartment of an institution; no transmission occurred to inmates in other apartments until a fresh case of typhoid fever was placed among the bacilli carriers. The management of bacilli carriers should consist mainly in instructing them of the danger of transmitting disease and of the necessity of caring for the proper disposal of their excreta. Isolation is possible only in cases of insane persons; it is otherwise justifiable only when the carriers of bacilli are employed in industries connected with the preparation and transportation of food. Operations, such as removal of the gall-bladder, have proved useless. Liefmann has tried the soured milk, prepared with Bulgarian bacilli, and recommended by Metschnikoff, in the treatment of three chronic bacilli carriers. Within a few weeks the typhoid bacilli disappeared from the feces. The author urges others to try this measure for ridding the gastrointestinal tract of typhoid bacilli in persons harboring them and not presenting any symptoms of typhoid fever.

Visual Auras of Epilepsy.—A. Rodiet and F. Cans describe the different kinds of aura preceding epileptic attacks which may be referred to the eyes. They include troubles of accommodation photopsia, amolyopia, and ocular tension, followed by complete blindness for a short time. There are motor auras, including convulsive movements of the eyes, nystagmus, and winking. There are sessory auras, consisting of painful feelings in the eyes. Another type of aura consists of the seeing of colors, the inability to distinguish colors, macropsia and micropsia, seeing of lights and stars. There may be difficulty of accommodation. Personages are reproduced by the eye that are causes of fear to the patient, dressed in peculiar ways and colors. The faces grimace at the patient. Others see themselves surrounded with flames from which they must escape, or globes of fire pass before them and objects scintillate. Again, the patient sees blood. The authors cite six interesting cases, and end with the statement that these visions, colored or not, are generally frightful, and the expression and gestures of the patient indicate severe fright. Motions of defense may result in injury to other persons, and account for impulsive acts of which the patient is unconscious, but which make the epileptic dangerous to his surroundings. Such attacks are often followed by delirium.—*Archives de Neurologie.*

Book Reviews.

Essentials of Dietetics in Health and Disease. A Text-book for Nurses and a Practical Dietary Guide for the Household. By Amy Elizabeth Pope, Author with Anna Caroline Maxwell, of "Practical Nursing," and Instructor in Practical Nursing and Dietetics in the Presbyterian Hospital School of Nursing; Instructor in Dietetics in the Schools of Nursing of the New York Hospital, Mt. Sinai Hospital and Smith's Infirmary, Staten Island; and Mary L. Carpenter, Director of Domestic Science of the Public Schools, Saratoga Springs, New York. New York and London: G. P. Putnam's Sons, 1908.

The first part of this volume is occupied with the Principles of Dietetics, and contains chapters on: Food; digestion and absorption; milk and milk derivatives; eggs; fish; meat; plant foods; dietaries; feeding of infants and children; and diet in disease. The remainder of the book is taken up with numerous recipes. The work is written in a simple and lucid style, and should be useful to the class of readers for whom it is prepared. The practical portions of the book are, we think, superior to the more scientific sections; these latter, indeed, are occasionally inaccurate. For example, the opening sentence of the book is "Food is the chief factor in maintaining life"; we are inclined to think that oxygen occupies the chief position. It is also stated that there is one per cent. of hydrochloric acid in the gastric juice; most authorities give it as 2 or 3 parts in a thousand. The section on chemical abbreviations is unnecessary in a book of this description, and instead of correcting it in a future edition, it would be better to omit it.

Grundriss der psychiatrischen Diagnostik nebst einem Anhang, enthaltend die für den Psychiater wichtigsten Gesetzesbestimmungen und eine Uebersicht der gebräuchlichsten Schlafmittel. Von Prof. Dr. Raecke, Privatdozent und Oberazt der psychiatrischen und Nervenklinik in Kiel. Mit 11 Textfiguren. Berlin: August Hirschwald, 1908.

This is a small book intended, as its title indicates, to be merely a guide in diagnosis of mental disorders. Methods employed in neurological examinations are also outlined where they have a bearing on these disorders. The writer gives first a carefully prepared scheme for the anamnesis, comprising the heredity, development, and later life of the patient, and the further etiology, inception, and development of the psychosis; then the physical examination of the patient, and finally the mental examination. These general investigations comprise one hundred pages, and the special part, devoted to the diagnosis of the special forms of mental disorder and to the hypnotics most commonly employed in these diseases, occupies the remaining thirty-seven pages. The classification followed is that of Binswanger and Siemerling. Professor Siemerling writes the preface, and stamps the book with his approval. The examinations, both psychic and somatic, as outlined, are very thorough and along the lines of recent scientific investigation.

Gynecology and Abdominal Surgery. Edited by Howard A. Kelly, M.D., F.R.C.S. (Hon. Edin.), Professor of Gynecologic Surgery at the Johns Hopkins University; Gynecologist to the Johns Hopkins Hospital, Baltimore; and Charles P. Noble, M.D., S.D., Clinical Professor of Gynecology at the Woman's Medical College, Philadelphia; Surgeon-in-Chief, Kensington Hospital for Women, Philadelphia. Illustrated by Hermann Becker, Max Brodel, and others. Volume II. Philadelphia and London: W. B. Saunders Company, 1908.

The final volume of this handsome work contains chapters on Complications following operations, by G. B. Miller; Cesarean section and Porro-cesarean section, by J. F. W. Ross; Operations during pregnancy, by R. C. Norris; The operative treatment of sepsis in the child-bearing period, by B. C. Hirst; Extrauterine pregnancy, by J. W. Williams; Diseases of the female breast, by J. C. Bloodgood; Operations upon the gall-bladder, bile-ducts, and liver, by A. J. Ochsner; Operations upon the stomach, by B. G. A. Moynihan; Pyloroplasty, by J. M. T. Finney; Intestinal surgery, by J. B. Murphy; Operations for diseases of the vermiform appendix, by H. A. Kelly and E. Hurdon; Surgery of the Pancreas, by E. L. Opie; Surgical treatment of diseases of the pancreas, by S. H. Watts; Operations upon the spleen, by H. A. Kelly; Tuberculosis of the peritoneum, by G. B. Johnston; Penetrating wounds of the abdomen, by F. W. McRae; Hernia, by G. L. Hunner; Operations for inguinal hernia in men, by E. Martin; Use of drainage in abdominal and pelvic surgery, by B. M. Anspach; Surgery of the ureter, by H. A. Kelly, and Surgery of the Kidney, by C. T. Noble and B. M. Anspach. It is impossible to give an adequate idea of the contents of this volume; but each chapter is good of its kind, and many of the contributors are well known as authorities on their respective subjects, and noted for their literary ability as well as for their ripe knowledge and technical skill. The result is that in these volumes we have a series of monographs of value to the gynecologist and to the surgeon. It may be remarked, however, that Hirst's chapter on The Operative Treatment of Sepsis in the Child-bearing Period, is practically taken verbatim from his text-book on Obstetrics; and the same criticism applies almost equally to Williams' chapter on Extrauterine Pregnancy. Possibly this is all right, and doubtless when arranged between authors, editors, and publishers it is legally honest; but it is hardly fair to the purchasers of an expensive work to hand them, in two of the most important chapters, virtual reprints of what they are exceedingly likely to have already on their shelves. Most men have a decided objection to paying twice for the same article, literary or otherwise, and especially do they dislike to be given old articles in what they are led to believe is an up-to-date publication. We made a similar criticism on one of the chapters in the former volume. Bloodgood's contribution on Diseases of the Female Breast is one of the best in the volume, but he makes the term "abdominal" very elastic when he includes supraclavicular dissection and operation.

A Manual of Obstetrical Technique as Applied to Private Practice, with a Chapter on Abortion, Premature Labor, and Curettage. By Joseph Brown Cooke, M.D., Adjunct Professor of Obstetrics in the New York Polyclinic Medical School and Hospital, etc. Illustrated. Sixth edition, enlarged and fully revised. Philadelphia and London: J. B. Lippincott Co., 1908.

Reviewing a book which has gone through six editions in a comparatively short space of ten years, may be regarded as a rather difficult task. Its faults have probably all been noted by previous reviewers and their suggestions adopted, if considered suitable, by the author. In the present instance we find a work which in its sixth edition has been carefully rewritten and a variety of changes incorporated. The book is addressed primarily to the younger practitioners of medicine, who have had their theory in college and have perhaps witnessed a few cases of delivery in a maternity hospital. Their knowledge may be difficult to apply in private practice for obvious reasons. The writer has attempted to reach this class by eliminating the hospital idea and by bringing forward not the methods practiced at maternity institutions, but those which may be developed in the homes of the patients. Whatever favorable comment has been passed on previous editions may likewise be accorded to the present. The chapters on version, forceps, mutilating operations, and the induction of premature labor have been rewritten and extended. There are many commendable features in the book, although exception may be taken to some of the author's individual statements. Thus the recommendations accorded to the Tarnier forceps as an instrument to be purchased by a beginner, must be regarded as of doubtful value, the experience of many being that it is a highly dangerous instrument in the hands of any but the most experienced. Another statement which seems to require modification is that a woman during the eighth month of pregnancy, may be permitted to extend her walking to an average of six miles daily. There are many very valuable suggestions in the book for the conduct of pregnancy and labor and the entire subject matter is presented in concise and readily understood form. The illustrations are also worthy of comment, being entirely free from attempts at "artistic" effect.

A Manual of Prescribing; For Students and Practitioners of Medicine. By C. R. Marshall, M.D., Professor of Materia Medica and Therapeutics in the University of St. Andrews, Assistant Physician to the Dundee Royal Infirmary. London: J. & A. Churchill; Philadelphia: P. Blakiston's Son & Co., 1908.

This is the most solid and complete work on prescriptions and prescription writing that we have seen in a long time. It is written from the standpoint of the medical practitioner, hence it is not a treatise on dispensing. It contains very important chapters on incompatibility, and examples of incompatibility; the latter of these two chapters has full notes on all the prescriptions employed. There are two appendices to aid those readers who are unfamiliar with the Latin names of drugs and their preparations, and the names of medicinal forms; etc. An English-Latin vocabulary is also added for reference. The work is unusually accurate, and can be recommended to medical students as a safe guide.

Pharmacology. The Action and Uses of Drugs. By Maurice Vejux Tyrode, M.D., Instructor of Pharmacology in the Medical School of Harvard University. Philadelphia: P. Blakiston's Son & Co., 1908.

In this volume the author supplies the medical student with a small and concise text-book containing the essentials of pharmacology. Facts only are given, and scientific discussions on doubtful points are avoided. The general action of drugs is emphasized, but mention is also made of their uses and applications, together with the preparations and doses. Medical students and general practitioners will find the book useful for review purposes

Report from the Pathological Department, Central Indiana Hospital for Insane, 1903-1906. Indianapolis: Wm. B. Burford, 1908.

This is a volume of nearly four hundred pages. It comprises a summary of three years' work in the pathological department of this insane hospital; and consists chiefly of the clinical reports combined with the gross and microscopical findings in 147 autopsies performed during that time. The older mental classification is adhered to. There is apparently no special original work.

High-Frequency Currents. By Frederick Finch Strong, M.D., Instructor in Electro-Therapeutics at Tuft's College Medical School, Boston. With 183 illustrations in the text. New York: Rebman Company, 1908.

Dr. Strong defines high-frequency currents as electrical vibrations, artificially produced, which bear a certain relation to the currents which traverse the nerves in the maintenance of life in the human body. Being vibrations, rather than flowing streams of electrical particles, as he says, the high-frequency currents pass through the human organism without sensation. The development of these currents is ascribed to d'Arsonval and Ouidin, while their practical application has been mainly from the work of Tesla and Elihu Thomson; and the development of technique by the author, himself, who for ten years has been engaged in a clinical and laboratory study of high-frequency currents of various types. The present work is devoted mainly to the physical laws and methods of using various apparatus for the production and application of high-frequency currents. In this he has gone into most minute details and shows a thorough knowledge of the subject. Less than thirty-five pages of the book are devoted to actual therapy; but sufficient is outlined to indicate a greater optimism on the part of the writer than the teachings of clinical experience and pathology permit most of us to possess. We are willing to acknowledge, however, the usefulness of high-frequency currents in certain metabolic and other disorders and in some nervous affections, while expressing some doubt as to their utility in infectious and malignant diseases. Again, some patients may object to the time lost and trouble incurred in obtaining treatment by high-frequency currents. For example, to relieve and abort acute coryza the writer recommends Tesla vacuum treatment with a metal electrode over the solar plexus and vacuum electrode in the nostrils; and he states that "ten-minute treatments, given at intervals of three hours so long as the acute symptoms remain, should be given daily for a week after the attack has subsided. It is well," also, he says, "to terminate each seance with a five-minute application of (the author's) high-frequency wave current applied with electrodes at the base of the brain and over the solar plexus." All for an attack of acute coryza. The author believes, however, thoroughly in the wide therapeutical application of high-frequency currents, and will soon publish, he says, a treatise on the subject.

Applied Surgical Anatomy, Regionally Presented, for the Use of Students and Practitioners of Medicine, by George Woolsey, A.B., M.D.; Professor of Anatomy and Clinical Surgery in the Cornell University Medical College, Surgeon to Bellevue Hospital, Associate Surgeon to the Presbyterian Hospital, Fellow of the American Surgical Association and of the New York Academy of Medicine. Second Edition, enlarged and thoroughly revised, with 200 illustrations, including 59 plates, mostly colored. New York and Philadelphia: Lea & Febiger, 1908.

In spite of the number of recent works on surgical anatomy, it is not surprising to see a second edition of this book; for from its first appearance it was recognized as combining in an unusual degree the two important features of accuracy of statement and clearness of expression. The second edition represents a careful revision; and the subject matter has been elaborated where it seemed necessary. The sections on cerebral localization, craniocerebral topography, abdominal viscera, pelvic viscera, and spinal cord have been rewritten or amplified. There is an admirable summary of the present knowledge of the parathyroids. Altogether the volume has been enlarged by about eighty pages and almost the same number of illustrations. The work is of equal value to the surgeon, the general practitioner, and the student; it is not only surgical anatomy, but also anatomical surgery and anatomy applied to medicine (as well as to surgery). It is a most useful and satisfactory volume.

The Therapeutics of the Circulation. Eight Lectures Delivered in the Spring of 1905 in the Physiological Laboratory of the University of London. By Lauder Brunton, Kt., M.D., D.Sc., LL.D. (Edin.), LL.D. (Aberd.), F.R.C.P., F.R.S., Consulting Physician to St. Bartholomew's Hospital. Published under the auspices of the University of London. With 240 illustrations. Philadelphia: P. Blakiston's Son & Co., 1908.

It is always a privilege to hear a lecture by Sir Lauder Brunton, at least so say those who have enjoyed it, and we can well believe it when we know the pleasure of reading any of his lectures on a subject in therapeutics. In this charming book are eight lectures delivered in the spring of 1905 in the physiological laboratory of the University of London, in accordance with the general purpose expressed in the establishment of the laboratory, "to present the results of recent investigations by the investigators themselves, orally and with experimental demonstration in the lecture-room, and outside the lecture-room by monographs approved by the university." The lectures are said to be on the therapeutics of the circulation, but the author is well along in the course before he refers in any but the most cursory way to the question of treatment. He begins with the physiology of the circulation, including the methods and instruments employed in the measurement of the blood pressure. Then comes a consideration of the pathology of the circulation, followed by a discussion of valvular diseases, and finally the lecturer takes up the method of treatment in cardiac diseases. The reader has no regrets over this division of subjects, and the delay in coming to the title subject, for the section on physiology especially is most interesting and instructive. The author was a pupil of Kronecker, to whom he dedicates the book, and his work contains many references to the views of this physiologist which are not familiar to all American students of the circulation. Among the various sphygmomanometers pictured and described we note Janeway's, but the author does not appear to be familiar with the simple and ingenious device of Bishop of New York. The book is throughout most practical and instructive, yet withal as entertaining as a novel.

Vaccine Therapy and the Opsonic Method of Treatment. A Short Compendium for General Practitioners, Students, and Others. By R. W. Allen, M.D., B.S. (Lond.); Late Pathologist to the Royal Eye Hospital; Late Gull Student of Pathology, Guy's Hospital. Second Edition. Philadelphia: P. Blakiston's Son & Co., 1908.

The author here presents the latest evidence in favor of the modern opsonic treatment of disease. He shows enthusiasm throughout, and is an evidently ardent supporter of these much disputed methods. In the present state of our knowledge we believe that a more conservative attitude would be in greater accord with the facts, but enthusiasm is necessary when investigating new ideas and trying them thoroughly.

The first chapter deals with the nature of opsonins, their site of formation, and their fate in the organism. The following chapters give the general principles involved in vaccine therapy, the regulation of dosage, the methods of raising the index, and the determination of the negative and positive phases. The question of the accuracy of the method of estimating the opsonic content of the blood is taken up, and the writer acknowledges the difficulty and delicacy of the operations. The following chapters deal with the preparation of the various vaccines for tuberculosis, staphylococcus, and streptococcus infections, gonorrheal, catarrhal, typhoid, and other diseases. The author throughout shows that he is conversant with his subject, and that he believes that future medical practice will employ these methods to replace those now in use.

L'examen fonctionnel de l'intestin. Par le Prof. Dr. A. Schmidt. Traduit par le Dr. R. S. Kolbé. Paris: Vigot Frères, 1909.

Schmidt's work on the functional examination of the intestine by means of his test diet is quite well known. The present book is an excellent translation of the original. A few drawings have been added to the text and increase its value.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held February 26, 1909.

DR. H. SEYMOUR HOUGHTON IN THE CHAIR.

A Study of Eunuchoidism in Its Various Aspects, and Its Bearings to Allied Pathological States.—Dr. B. ONUF presented a communication on this subject. Eunuchoidism, he said, bore a close relation to eunuchism, symptomatically, as well as etiologically. In both cases the symptoms were due to persistent loss of internal secretion of the testes, sustained at any early age, or congenital. Eunuchism was brought about by the removal or destruction of the testes by mechanical means; eunuchoidism by traumatism or pathological processes affecting the testes more or less directly, or through nervous influence. Cryptorchidism also might give rise to eunuchoidism, with loss, in some cases seemingly with preservation, of the fertilizing faculty. Eunuchoidism might be either congenital or acquired. The known congenital cases were pseudohermaphroditic states associated with testicular aplasia or hyperplasia, cryptorchidism, anorchidia, and congenital atrophy of the testes. A sharp line between anorchidia and congenital atrophy probably did not exist, anorchidia being, according to LeDentu, probably an atrophy of the testes acquired at a very early period of fetal development. Eunuchoidism might also be hereditary (Sainton, Onuf), and might be transmitted through females. The cases of acquired eunuchoidism were mostly those of acquired atrophy of the testes, namely, traumatism of the testis or epididymis, including torsion of the spermatic cord; hereditary syphilis affecting the testis (Dupré); orchitis of the acute infectious diseases, particularly mumps and, according to Wolbarst, malaria (perhaps also smallpox); injury or diseases of the nervous centers or nerves controlling the nutrition of the testis, *i.e.* lesions involving the spermatic plexus or lumbospinal cord, or lesions of the neck or the occiput, cerebellum or cervical sympathetic. Eunuchoid facies with, to all appearances, normal sexual organs, might be due to disease of the so-called interstitial gland of the testis, with preservation of the external secretion, containing the spermatozoa; in other words, it might represent a philogenetic reversal of type, such as was seen in the Indian race and many Eastern people. Regarding power of fertilization and vitality of the offspring, the histories of the married cases of eunuchoidism showed on the one hand an expected result, *i.e.* a large percentage of sterility associated usually with complete absence of emissions on the part of the eunuchoid husbands; on the other hand, the relative frequency of abortion in those cases in which fertilization was alleged to have occurred, pointed to a lack of vitality of the offspring. Regarding the ultimate viability of living offspring of eunuchoids, the figures did not give definite information. Both power of procreation and vitality of offspring, however, apparently depended to a great extent on the degree of sexual hypoplasia or atrophy, as would naturally be expected. Nevertheless, conclusions as to the power of procreation and vitality of offspring from the size of the sexual organs and particularly of the testes were by no means reliable. The sexuality of eunuchoids was gauged predominantly by the degree of testicular hypoplasia or atrophy accompanying it. The more marked the latter, the greater the loss of sexual desire, sexual potency, and power of fertilization; but the impairment of sexual desire and potency seemed to depend more on the degree of reduction in size of the penis, than on that of the testes. No case presented unquestionable aberrations in the domain of the sexual psyche other than those due to absence or diminution of the sexual [illegible] Actual perversion of sexual [illegible] particularly in the direction of homosexual feeling [illegible] attraction toward the same sex, was not proven in any of the cases, although one case was slightly suggestive of psychic hermaphrodisia while, in another case, erotogenic factors seemed to cause disgust or aversion rather than erotism. The general mental traits of eunuchoids of marked degree were child-like simplicity, effeminacy of manner, child-like emotivity, domestic inclinations, lack of courage, to which there were notable exceptions, however, even in the marked cases. So far as the speaker's opportunities of observation went, which, though unusually favorable as to the number of cases seen, were subjected to certain restrictions, applying also to the sexual psyche, he said he was unable to substantiate even for the sexually typically cases of eunuchoidism, as a class, the low moral qualities attributed by many authors to eunuchs, in spite of the close affinity of one class to the other, and in no case were general ethical shortcomings found that did not come within physiological boundaries. Neither had he been able to confirm in two personally observed cases of eunuchoidism from accidental traumatism, the low mental and particularly the low ethical standard claimed for eunuchs. In none of the cases of eunuchoidism under observation was any psychosis stated, but two cases were reported as imbeciles to the immigration authorities. Eunuchoidism in a certain class constituted a social menace, chiefly in relation to matrimony and because of the possibility of the hereditary transmission of the defect.

The Further Separation of Antitoxin from Its Associated Proteins in Horse Serum.—Dr. EDWIN J. BANZHAF read this paper. He said that the observation of Stark, who showed that when egg albumin was heated for one hour at 56° C. a portion of it was converted into a body which, because of its precipitation and solution reactions, and also because its composition was obviously a globulin, excited his curiosity as to the resulting conditions in antitoxic horse serum. In this observation citrated plasma and partially purified antitoxin solutions were heated. With this in view, he carried out a large series of experiments with results that were rather gratifying as to further purifying the antitoxin at least 50 per cent. more than by the former methods. This was extremely interesting from the scientific standpoint in that it opened a new field for further investigation, which might throw some light on the chemical characteristics and the nature of the antitoxins. Soon after the protective and curative value of diphtheritic antitoxin serum was assured, investigators attempted to isolate the active agent. The earlier attempts included precipitating the proteins of the antitoxin serum with practically all known protein precipitants. Later the investigators confined their attempts to precipitating the globulins containing the antitoxin with saturated magnesium sulphate and with half saturation of ammonium sulphate. Attempts to isolate and establish the non-protein nature of antitoxin from the standpoint of its digestibility with trypsin had so far failed. The methods which had been proposed for the partial isolation and concentration of antitoxin were for the most part tedious and peculiar. The earlier investigators located the protein which carried the antitoxin and noted the globulin-like characters of this active agent. None of these methods, however, was practical for therapeutic use. He said that Park's suggestion of fractioning the globulins in the serum with ammonium sulphate was taken up by Gibson and himself with very satisfactory results. In the high fraction giving a concentration separating the remaining unconverted albumin from this series, the increase of antitoxic units per gram protein, was 60 per cent after six hours' heating, increasing to to 78 per cent. after forty-eight hours. The seventy-two-hour heating showed an increase of 73 per cent. over the native serum. Citrated

plasma under the same conditions gave practically the same results. Gibson's antitoxic globulin solution (blood alkalinity) containing only that globulin in saturated sodium chloride solution was heated under the same conditions. The potency loss was 5 per cent. for the six-hour period, and an increasing loss up to 23 per cent. for the seventy-two-hour period. The soluble globulin converted into an insoluble condition (in saturated sodium chloride solution) was 30 per cent. after six hours' heating, increasing up to 47 per cent. after seventy-two hours. The increase of antitoxic units per gram proteid was 37 per cent. after six hours' heating, increasing up to 53 per cent. for the twenty-four hours. This work which was being carried out further was practical and scientifically important, and might throw some light on the chemical characteristics and the nature of the antitoxins.

The Value of the Milk Free Diet and Enteroslysis in Typhoid Fever.—Dr. Robert Coleman Kemp read this paper and said that he would endeavor to demonstrate that the milk free diet in typhoid fever, first suggested by A. Seibert, was based upon absolutely scientific facts. In addition to the changes in the lymph glands of the small intestine, notably of the ileum, in about one-third of the cases the glandular elements of the large intestine were involved; and in all cases an acute catarrhal condition existed throughout the small and large intestine. This important feature seemed to have been lost sight of when the question of a correct diet was brought up for consideration. In discussing the diet in typhoid fever, he especially desired all to keep in mind the disturbances of the functions of the gastrointestinal tract, the presence of the universal intestinal catarrh, and the condition of general infection. During the past few years there had been practically three methods of diet advocated in typhoid fever, viz., (1) the full diet (rich albuminous); (2) milk diet, with milk, or fermented milk, as a basis; (3) fluid diet without milk, by means of strained soups. As the result of the use of the milk free diet in typhoid fever, Dr. Kemp said he had noted the tympanites and temperature lessened when the milk was withheld, and increased when milk was again administered. With milk free diet, his patients had had much less tympanites, the temperature had been much lower, and the disease had run a milder course. In fact, by this method, combined with rectal irrigation and the ingestion of large quantities of water, the temperatures had kept generally below 102.5° F., so that the friction bath (Brand), or the Nauheim bath could be omitted. The following, constituting milk free diet, were of service: strained rice, barley, oatmeal, and chicken broths. Strained thin pea, potato, or vegetable soups could be occasionally given for variety. From one quart to a quart and a half, as the maximum amount of the broths, should be given during the twenty-four hours in divided doses every three or four hours, the last feeding no later than 9 P. M. In marked nephritis he omitted the chicken broth. Gelatin had a certain value as a food. Voit had shown that though it did not build up new tissue, it might diminish tissue waste. He gave stout people no gelatinous food. Gelatin lessened the tendency to hemorrhage, but was contraindicated where there was thrombosis. A large quantity of water should be administered, to which should be added dilute sulphuric or nitromuriatic acid, rendering the water slightly acid to the taste; this caused a stimulation of the gastric secretion. When the temperature reached 102.5° F. he stopped all nourishment, giving only water, three or four quarts in the twenty-four hours, as an aid to elimination through the kidneys; he flushed the bowels more frequently and employed alcohol and water sponging. As to stimulants, he found strychnine and camphorated oil preferable to alcohol.

With regard to the value of intestinal irrigation in typhoid fever, certain scientific facts should be remembered: (1) Fatal autoinfection could occur with constipation; Holt had reported such cases; (2) the stool consisted in large part of bacteria, many millions in number; (3) bowel movements occurred even after the withholding of food, and they consisted chiefly of bacteria, mucus, epithelia, etc.; (4) If, after operation, a portion of the intestine was made to terminate in a blind pocket, accumulation might occur therein and even ulceration and perforation result, though no food remnants entered the pocket. Though the bowels might have been supposedly thoroughly cleansed by catharsis, and only water or soluble broths had been administered, it was surprising the amount of material cleared out by enteroclysis. He believed that the use of enteroclysis was one of the most important features in the treatment of typhoid fever. The only contraindications were hemorrhage and peritonitis. By the irrigations, contents of the small intestine were emptied into the large intestine, and this in turn cleared out; absorption from accumulation in the colon and rectum was prevented, and hence toxemia was lessened and the temperature was reduced; gas, if present, was removed from the bowel; the large intestine was kept clean, and elimination of the toxins, through the diuretic action of the injections on the kidneys, was promoted.

Dr. A. Seibert said that he had followed the method described by Dr. Kemp for the last twenty years; during this time he had never given a typhoid fever patient milk, nor had he given an infant or young child, suffering from enteritis milk in any shape or form; in such cases he never gave mother's milk, pasteurized or sterilized milk until the enteritis had been cured. The success of certain treatments in certain diseases depended largely upon the selection of the cases. To prove his position taken in regard to the giving of milk in typhoid fever, he said that if one used the milk-free diet for a certain period of time, and then administered milk, even in small quantities, the fever and pulse would go up, only to come down when the milk was omitted; one could make the temperature and pulse go up and down by adding milk, or leaving it out of the diet. Leaving milk out of the diet in typhoid fever was practically a prophylactic measure, because it prevented the formation of toxins. Milk was one of the best foods for the typhoid bacillus, but a poison to the patient. Twenty years ago he used a catheter to irrigate a typhoid fever patient; a hemorrhage resulted and he had never used a catheter or tube since. The buttocks of the patient were elevated and plain water was allowed to run into the intestine; the nozzle of the syringe was only one inch through the anus. This method of irrigation he used twice a day, and without any inconvenience on the part of the patient.

THE WILLIAMSBURG MEDICAL SOCIETY.

Stated Meeting, Held February 8, 1909.

Dr. William Linder in the Chair.

Demonstration of Roentgen Plates of Stomach.—Dr. Charles Eastmond of Brooklyn demonstrated a series of plates showing the facility of diagnosis of gastroptosis by this means.

Demonstration of Corset for Splanchnoptosis.—Dr. A. Ernest Gallant of Manhattan made this demonstration. He said that on a careful review of 7,266 case histories, he had treated 456 for virceral ptoses. These were found in both sexes, at nearly all ages, and especially in young nulliparæ and women who had borne children. In a large proportion the lower part of the face was deeply furrowed and drawn and the attitude was that of one lacking in muscular vigor, with shoulders stooping and a doubled-up way of sitting. In nulliparæ there was an absence of fat, the hips were narrow and unequal;

there was a long, slender waist, a hollow epigastrium, protuberant hypogastrium, scoliotic back and a disproportion between the length of trunk and legs. Of the several ectopic viscera, the most prominent and easily palpable was the kidney. This either gave rise to no symptoms, or when prolapsed on the right side, and compressed by corsets and waistbands, produced Dietl's crises, or when descending intermittently on the right side induced hydronephrosis, or slight descent of a chronically congested right kidney dragged on or compressed the bile duct and caused acute jaundice, or acute traumatic dislocation of the kidney, chiefly the left, produced hematuria. The most frequent and important of the visceral ptoses was that of the stomach and colon, insidious in development, detrimental to health, frequently overlooked, intractable to treatment, damaging to other viscera, dragging down the liver, spleen, and heart, interfering with respiration, circulation, alimentation, nutrition, and excrementition. Surgical treatment was to be resorted to only as the last resort. All except 1 per cent. of the cases of symptomatic movable kidneys could be cured symptomatically by wearing a corset. The three most powerful agents at one's disposal for visceral replacement were posture, massage, and exercise. In the most severe cases it was necessary to keep the patient in bed for several weeks. During this time use was made of the stock binder to afford support. The use of a corset laced tightly at the waist, while it served to relieve kidney symptoms, viz., Dietl's crises, hydronephrosis, jaundice, and hematuria, on the other hand, it intensified the gastritis, constipation, malnutrition, etc., of enteroptotic origin. The corset to be effective had to be made to order, with the following essential features: it had to conform to the latest fashion; at the bottom, the front steels had to overlap the upper half-inch of the symphysis pubis; it had to reach down low and fit very snugly around the hips, stretching very tightly across from one anterior superior spine to the other, to flatten and reduce the hypogastrium to a minimum; to prevent constriction, the circumference was to be equal to that of the natural waist, with a well-marked incurving of the sides at the waist, to support the kidney, to prevent the corset slipping upward, and to afford a fashionable outline to the figure; at the back and sides, the upper portion had to accurately fit the thorax, while in front ample room had to be provided for the replaced stomach, as any pressure on the epigastrium induced unbearable pain and discomfort. Below the waist the corset had to be inelastic and inflexible, while above the waist it permitted free play to every motion of the trunk. For thin women, with hips deficient in fat, hair pads had to be stitched inside the lower part of the corset. The one lace was inserted at the first eyelet above the waistline and continued down to the bottom of the corset. In the upper part a thin, flat, hat elastic was inserted, and loosely drawn enough to keep the garment in close contact with the thorax. The corset had to be ordered, fitted, and adjusted with the same care and attention to detail as an orthopedic apparatus. After wrapping the corset loosely around the body,, the patient was to lie down on the bed, flex the legs to a right angle, and while in this position to massage the abdomen, stroking upward, for ten minutes. She was then to draw the corset well down over the hips and to fasten in front, beginning with the lowest hook. Without lowering the hips, she was to draw in the lace at the back as tightly as possible, tying it at the back close to the last eyelet. The corset was not to be pulled down after the front had been fastened, and the hips were not to be lowered; nor the patient to stand or sit up until the back lacing was drawn as tightly as it could be drawn. The tests of a properly fitted and adjusted corset were the front steels always overlapped the upper border of the symphysis; the lower or suprapubic area was flattened and fitted so snugly that when lying down the fingers could be barely inserted between the corset and the bone. The replaced stomach was noticeably prominent within the upper portion of the corset and caused a distinct bulging of the epigastrium. On rising, sitting, or walking, the corset did not hitch upward. The contraindications to the use of the corset were: when the kidney was not replaceable above the waist line; when the stomach was held down below the umbilicus by peritoneal adhesions; in the presence of pus tubes or tumor in the pelvis or abdomen.

Demonstration of the Rose Bandage.—Dr. Adolph Bonner of Brooklyn demonstrated this method of relieving abdominal ptoses by means of a properly applied support of adhesive plaster.

The Diagnosis and Treatment of Gastroptosis.—Dr. Joseph Merzbach of Brooklyn read this paper. Following the method of Virchow in seeking an anatomico-pathological basis for the science of medicine, efforts had been made to give an anatomical foundation for the protean group of symptoms grouped under the designation "nervous dyspepsia." Kussmaul had been the first to point out the difference between functional or apparently functional disorders and displacements of the abdominal organs. He had been followed by Glénard, Meinert, and many others, some of whom had gone too far in emphasizing the significance of these malpositions. The difficulty of forming a clear judgment about these conditions and their interdependence, and apportioning the proper share to anatomical influences on the one side and nervous impressions on the other, was explained on three grounds, as follows: First, the difficulty of defining the exact boundary between a neurosis and organic lesions; second, the fact that a neurosis and organic lesions were frequently associated, and third, the uncertainty as to the exact position of the stomach. It had been supposed that the greater curvature of the stomach represented the lowest part of this organ, until some recent radioscopic investigations had shown that in the upright position the lowest part of the stomach was the pyloric region, which was horizontal, with the cardiac portion in a vertical position. Although other investigations had been at variance with these, it was nevertheless certain that the normal stomach was such a rare event that its occurrence might be considered pathological. The speaker excluded from consideration the acute gastroptosis that occurred physiologically in connection with the act of digestion, or as the result of overfilled intestines. Gastroptosis caused by pressure from above, as through an empysema or a left-sided pleuritic exudate, could, of course, be diagnosticated only in patients the position of whose stomachs had been known previous to the occurrence of the pulmonary condition. The speaker next mentioned the more important of the many etiological factors of chronic gastroptosis. The view of Glénard that the primary cause was a weakening of the hepatocolonic ligament had been abandoned, and it was generally acknowledged that congenital predisposition favored the occurrence of a gastroptosis. The most important of the exciting factors were the pressure by corsets and the weight of skirts fastened around the waist. The liver was not only subjected to anatomical change, but also tended, as the result of this pressure, to force the stomach downward and to the left. Other factors were frequent parturition without the necessary post-puerperal cure, acute diseases producing atony, insufficient and improper nutrition, inflammatory adhesions, and physical and mental overexertion. The frequent occurrence of gastroptosis among school teachers showed that continued mental strain was an etiological factor of great importance. It was especially in this class of cases that were found the profound disturbances of the nervous system which were usually associated with marked displacement of the abdominal viscera. In fact, a great many

patients came for persistent severe hemicrania, or objective and subjective vertigo, palpitation of the heart, sachy cardia, presternal pressure and precardial pain, backaches, and other symptoms. In other cases the digestive complaints predominated, ranging from a mere postprandial discomfort to a most excruciating pain in the epigastrium or some lower point. Appetite was usually lessened, nausea occurred frequently, and vomiting very rarely. The gastric chemism varied from hyperacidity to normal and sub or anacidity. Motility was not much impaired. This was decreased in proportion to the degree of constipation which was nearly a constant concomitant of splanchnoptosis. In addition to these there were an array of complaints, partaking at times more of the character of hysteria; at others, of neurastheria, and sometimes of hypochondriasis. It was this constant intermingling of functional disturbances with evidences of an organic lesion that surrounded the recognition of splanchnoptosis with some difficulty. The statement of the patient that he felt something moving about in his abdomen was not to be relied upon in the formation of a diagnosis. In reaching this, inspection was of value in the case of a very thin abdomen. In this case there was seen not infrequently the lesser curvature bulge forward below an epigastric space that was sunken in; the greater curvature appeared with greater or less distinctness below the umbilicus for a varying distance. Palpation was not satisfactory. Percussion was looked upon by many as a difficult and misleading method. The difficulties were only in the differentiation between the colonic and gastric resonance. Until the acoustic differences could be appreciated it was a matter of patience to determine the position of the greater and lesser curvatures and the pyloric end. When the splashing sound was heard, its extent gave the outlines of the stomach with fair accuracy. One frequently succeeded in obtaining splashing after the patient had taken one or two glasses of water. Insufflation of the stomach with air or CO_2 had been abandoned by the speaker, not only because of the discomfort it caused, but also because it was dangerous, and at any rate unnecessary on account of the sufficiency of other methods for diagnostic purposes. Transillumination of the stomach by means of Einhorn's lamp was not absolutely reliable, and was only occasionally used as a control of the findings obtained through other channels. The Roentgen rays gave such unimpeachable results that they promised to rank among the foremost means for the recognition of gastric displacements. The defect that they necessitated the introduction of a large quantity of bismuth (℥i to ℥ii) which by its weight stretched the stomach beyond its norm, would probably be remedied sooner or later by some modification of the ray medium. The diagnosis of a displaced kidney, of a prolapsed liver, the evidence of a dislocated colon or a cardioptosia aided in the recognition of the changed position of the stomach. In differential diagnosis from dilatation of the stomach it was noted that in gastroptosis the size of the stomach was normal or even subnormal, while it was increased in dilatation. In the latter there were stagnation and fermentation which were absent in simple displacement. The prognosis of gastroptosis was excellent provided it was not associated with marked atony and dilatation. The speaker had seen the position of the stomach improved, but had never observed a return to absolutely normal anatomical relations. The preventive treatment was more important than the curative. It was the duty of physicians to insist upon a long rest after the acute diseases affecting children, for the heart was not the only muscle attacked by atony. In seeking to protect the growing girl from the baneful effects of corsets and skirt bands fastened around the waist, fashion was an adversary to be encountered, and had always come out victorious in the battles waged against it by physicians. The straight-front corset was the less deleterious. Gymnastic exercises during childhood and adolescence were important. One of the most important preventive measures was a sufficient amount of rest after childbirth, the duration of which was to depend in each individual case upon the tone of the uterus and of the abdominal muscles. If the patient was compelled to rise before the normal tone was restored, she was to be provided with a proper abdominal supporting bandage. Of curative measures rest was the most important: absolute rest of body and mind in the severe types, and one to two hours' rest after the midday meal in those of a milder character. Where the finances of the patient permitted, sojourn in a well-managed sanatorium, of which there were but very few in this country, was desirable. The rest was to be combined with hydrotherapeutic measures, as the tepid pack, the cold sponge and rub, a short douch to the abdomen, the cold compress, and so forth. Careful and mild massage aided in strengthening the abdominal muscles and in hastening the sluggish passage of food in the stomach and intestines. The effect of electricity in the form of the galvanic or faradic current was mainly that of a transient suggestion. A mild vibratory massage was sometimes helpful in overcoming the constipation. The most important factor in overcoming the intestinal sluggishness was diet, which could not be of a schematic character in a condition in which the digestive capacity varied within such wide limits. The patients could never be cured unless their constipation was overcome by other means than medicines. As regards diet: milk, if well borne, was to be given in small quantities not exceeding four ounces at a time. Cream was better, when given in mashed potatoes, spinach mixed with carrots, or in cereals, or with cocoa. Toast was advisable because it permitted the ample addition of butter. Bacon was useful. In patients in whom the evidences of atony were not marked, the addition of raw fruit, broiled meats, graham bread, honey, etc., proved useful. Boiled and stewed fruit were well assimilated, even in a weakened digestion. The meals were to be prescribed in such a manner as to allow the accumulation of adipose tissue that would benefit the mesenteric support in the most marked manner. Stronger muscles and a larger amount of fat gave the abdominal organs the natural support to which they were entitled. For anorexia and discomfort after meals, psychotherapy was to be resorted to before drugs. Strychnine in small doses with or without dilute hydrochloric acid was sometimes useful as an appetizer. The same indication was fulfilled by tincture of nux vomica alone or in combination with the fluid extract of condurango. Bromides, valerianates, or both were required very frequently. Hydrastis canadensis that had been recommended by Dr. Fuhs had been employed in some cases of splanchnoptosis with atony, with good results. Of the laxatives, only the mildest were to be used, when necessary; of these, cascara sagrada, phenolphthalein, and Carlsbad salts were the best. The mechanical modes of treatment, provided that they really supported the abdominal organs not only in the horizontal but also in the perpendicular position, were at any rate but temporary expedients, and were to be used only until the normal equilibrium was obtained. When they were worn, exercise had to be insisted upon, lest the bandage or belt injured the patient more than it benefited him. Among the mechanical supports pregnancy occupied at least the position of a temporary aid. In cases of splanchnoptosis associated with lesions in other parts of the body, particularly with affections of the pelvic organs, it was the opinion of conservative gynecologists that rest and general treatment were to be tried before resorting to the knife (leaving aside acute suppurative cases, in which operation was indicated as a matter of course). In those cases there were noticed frequently not only the disappearance of chronic exudates and an improved position of the

ovaries, but synchronously a great improvement in the displacement of the abdominal organs. In splanchnoptosia associated with perineal and cervical lacerations the plastic operation not infrequently remedied the higher condition. It was difficult to decide whether to postpone the operation until the abdominal condition had improved or to undertake the treatment of both conditions at the same time.

Dr. Jacob Fuhs of Brooklyn said that the most frequent cases seen were the bad ones, in which the stomach mostly was displaced. In the ptosis of some single organ there was usually some other etiological element besides lack of support. In the case of the stomach it could be adhesions forcing the organ down from above, or a pyloric stenosis causing stagnation of the stomach contents. The recognition of a displaced stomach in the early stages was not easy. In a case of gastroptosis one could frequently feel organs behind the stomach better than usually. Thus an endurated pancreas could be readily felt, and also the pulsations of the aorta. Most of the patients had no bulging abdomen in spite of the gastroptosis. It was necessary to feed the patients up, beginning with one-quarter of a pound of butter a day and rapidly increasing the amount to one-half a pound a day. School teachers suffering from gastroptosis were to lie down for a couple of hours every day after their work and to spend most of Saturday and Sunday in bed. A vacation of from four to six weeks was better. Ptosis did not go on to dilatation except when there was pyloric stenosis. Operation was to be resorted to only in the extreme cases with dilatation.

NEW YORK ACADEMY OF MEDICINE

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held February 25, 1909

DR. JOHN O. POLAK IN THE CHAIR.

A Case of Hermaphroditism.—Dr. S. M. Brickner presented an individual, forty-eight years old, who was born in Sweden and supposed to have been a girl at birth; female attire was used until the age of ten years, when male attire was donned and he had continued to live as a male ever since. His build was distinctly that of a woman, but the pelvis was of the male type. The breasts were large and pendulous. The skin was soft, and the hair very fine. He had a well developed prepuce, and a rather long clitoris, within which was a small fold but no urethra. The urethra was situated one and a half inches below the insertion of the clitoris, while below the urethra was the perineum of about one and a half inches extent. Each side of the fold contained a movable body, either testicle or ovary. Just below the urethra and where the entrance to the vestibule would be in a normally built woman was a blind pouch with a distinctly constrictor action.

Struma Ovarii Colloides.—Dr. Robert T. Frank presented this specimen. Only twelve such cases had been reported in literature. Dr. F. C. Wood, at the January meeting of the New York Pathological Society, presented such a specimen, with several others intermediate in form. The specimen was a tumor, the size of a peach, containing the following tissues: There was one molar tooth with a smaller piece of bone attached; the bone had Haversian systems. There was found also a corpus luteum, perfectly normal, and the sole representative of ovarian tissue. The rest of the tumor was composed of colloid material. It could not be differentiated in section from the ordinary colloid goiter; it was like a normal thyroid gland in a few areas. Macroscopical and microscopical drawings were presented. It was at first thought that these tumors were due to metastases of either normal or malignant thyroid tissue. Normal thyroids had been found to produce metastases in bone; in one instance, in the jaw, and in another in the skull. After complete removal, they recurred. In a study of dermoids by Pick, six out of twenty-one contained thyroid tissue. The interpretation was that this was a part of a teratoma, or compound tumor, in which thyroid tissue had overgrown the rest, and was the only tissue to develop. This was not unusual. There were all transitions between a dermoid containing thyroid tissue and teratoma containing various structures besides thyroid tissue; in some cases almost nothing but thyroid had been found. Walthard had noted three such cases. In one-half of the cases ascites was present.

Electric Light Equipment for Operating in Private Houses.—Dr. LeRoy Broun presented this outfit. The arrangement was a box, 15″ x 18″ and 18″ deep. The complete weight was thirty-two pounds. It contained a large spool having five hundred feet of electric light cable. In another partition was an aluminum reflector with four thirty-two candle-power lights; also one thirty-two candle-power hand light and reflector. The attachment socket for both of these reflectors was on the flange of the spool, and wired to the inside of the long cable. The outside end was provided with a screw plug and could be unwound at will to reach the source of electricity, being long enough to reach two-thirds of a long block and over. The weight was so small that the box could be readily placed in a carriage and carried anywhere.

Tuberculosis and Pregnancy.—Dr. Charles C. Trembley of Saranac Lake, N. Y., read this paper. A compilation of the histories of tuberculous women who had borne children revealed an astonishing number who attributed the onset of their symptoms to pregnancy or childbirth and, without doubt, the number could be greatly augmented by further investigation. Only by careful questioning was evidence elicited of cough, expectoration, afternoon rise of temperature, and slight hemoptysis, occurring several months previous. Conflicting opinions were advanced by authorities as to the period during which the initial symptoms most frequently appeared. His personal observations led him to believe that the puerperium exhibited a predominant number, although any stage might witness its onset. Whenever the primary symptoms became apparent during the early months of pregnancy, it was undoubtedly due to the nausea, loss of appetite, and the mental and physical depression so frequently associated; should the active symptoms continue, it resulted either in premature delivery or the birth of an ill-nourished child. The puerperal manifestations of tuberculosis were fairly uniform. For the first few days the patient complained of lassitude and exhibited but little interest in her surroundings, was irritable, had little or no desire for food; the temperature might be normal. Generally about the third or fourth day, though occasionally not until the tenth or twelfth day, the temperature rose suddenly to 103° or 104°, with a concomitant rise in the pulse rate, frequently preceded by a chill, with the lochia normal. The temperature records then showed from 99° to 100° in the morning to 101° to 103° in the afternoon. The subjective symptoms were entirely disproportionate to the temperature and pulse. It sometimes happened that the patient was unaware of any elevation of temperature. There was practically a normal differential count, with only a moderate leucocytosis which accompanied pregnancy. In the next few days a slight, catchy, dry cough made its appearance and commonly at this time, slight lancinating pains on deep respiration suggested pleuritic invasion. Before bacilli could be demonstrated in the sputum, the von Pirquet or Moro test might serve in diagnosis.

The following observations were based upon a review of 240 cases, nearly all being between the ages of 25 and 36. There were 113 multiparæ, and 127 who were primiparæ or had had a miscarriage. A positive history of tuberculosis originating or at least distinctly recognizable

after the birth of the child or during pregnancy was given in 151, or 63 per cent.; 103 showed their first symptoms during the puerperium. The predominant diagnosis of the puerperal onset of tuberculosis appeared to be bronchitis. Although 42 cases were recorded as having had a miscarriage, in only 3 cases did the history even suspiciously point to this as a starting point, and two of these were forced to resume their daily routine of work after having been in bed only one or two days. A history irrespective of pregnancy was given in 89, or 37 per cent. Of the 151 patients which showed their first symptoms during pregnancy or the puerperium, 44, or 29 per cent. were I-para; 68, or 45 per cent., were II-para, and 39, or 26 per cent., were III-para. Of these at present 80, or 53 per cent., were dead, and 71, or 47 per cent., were living. Of the 81 not traced to pregnancy or the puerperium, 30, or 34 per cent., were I-para; 41, or 46 per cent., were II-para, and 18, or 20 per cent., were III-para. Of these at present, 36, or 41 per cent., were dead and 53, or 59 per cent., were living. As regards condition on arrival in the mountains, the definite cases exhibited 29 per cent. of incipient and 71 per cent. of advanced and far advanced, the indefinite showing 34 per cent. of incipient and 66 per cent. of advanced and far advanced. The cases definitely traced showed 53 per cent. of deaths, and those not attributable to pregnancy showed only 41 per cent. This large percentage of deaths after pregnancy would seem to indicate that in these cases the protective influence noted during pregnancy had been removed, leaving a condition of lowered resistance to the action of the tubercle bacillus. Regarding the serious effect of pregnancy when occurring in the course of a tubercular process, in each and every case it was a menace to the future health of the woman. In permitting a phthisical woman who became pregnant to proceed to term, the physician must face a two fold problem: first, in regard to the effect upon the mother; and second, in regard to the effect upon the child. Among 45 cases of labor occurring in women known to have tuberculosis before fecundation took place, 27, or 60 per cent., died and two were still under observation and probably would die within the year. The children of tuberculous women were ill nourished, marasmic, and presented a strumous diathesis. The only rational course to pursue where pregnancy occurred in tuberculous women, and where it was recognized during the early months, was the radical method of intervention. The only cases that should call for hestitation were, (1) those which had been discharged as cured and had remained absolutely without symptoms for at least one year; (2) cases in the terminal stage with progressive signs; (3) serious dissemination complicating the pulmonary lesions.

The following results were based upon a series of 29 cases of therapeutic abortion which had come under his observation and exhibited striking contrast to the cases allowed to complete their pregnancy. They represented all stages of the disease, and all but one were induced before the fifth month. Of the cases considered, 3 were very active cases of an advanced type; 6 were mildly progressive cases of an advanced type; 4 were mildly progressive cases of an early type; 5 were quiescent incipient types, and 11 were quiescent advanced and far advanced. Of these, 11 were induced during the second month; 14 during the third month; 3 during the fourth month; and 1 during the sixth month. In only one instance was there a relapse as a result of the abortion, and this case quickly recuperated. Eighteen cases showed a gain of from 2 to 8 pounds within five weeks afterwards; five remained stationary, and six lost from 1 to 5 pounds. Of the total cases, eight had died, three as the result of childbirth.

Dr. Trembley concluded as follows: 1. Pregnancy was an etiological factor to be considered in the tuberculosis problem. 2. During the puerperium the disease showed its greatest activity although any month of pregnancy might witness its onset. 3. Mortality was greater among women showing their first symptoms during the puerperium than among those showing onset irrespective of pregnancy. 4. Mortality was greater among phthisical women who subsequently passed through labor than among phthisical women in general. 5. A tuberculous woman might conceive during any stage or phase of the disease. 6. Latent, quiescent, or arrested tuberculosis was almost invariably rendered active by a completed pregnancy. 7. Occurring in the course of more or less active tubercular disease, it almost invariably resulted in rapid progression, and frequently terminated fatally. 8. Patients should be instructed as to the detrimental results of pregnancy. 9. The offspring of tubercular women were generally weak and displayed a strumous diathesis. 10. When a phthisical woman was allowed to complete her pregnancy she should have the benefit of climatic treatment and the child should be separated from the mother at once. 11. Abortion should be practised in every instance when pregnancy was recognized in the early months, since it would enhance the woman's chances of recovery; but in the later months generalization was not feasible; each case must be considered individually. 12. Mortality and percentage of relapses were practically nil when abortion was induced before the end of the third month. 13. Premature delivery should not be considered in the later months of pregnancy unless the patient's condition absolutely demanded it. 14. Cases apparently cured having remained without symptoms or signs for at least one year, might be allowed to go to term, but should be under careful supervision. 15. In all cases allowed to complete their pregnancy, the labor should be terminated rapidly and with as little exertion as possible on the part of the woman.

Dr. Charles Jewett said he was especially gratified that Dr. Trembley took so definite a stand on the question of early interference; with few exceptions, Dr. Jewett believed that pregnancy complicated with tuberculosis should be terminated early in the disease if any benefit was to be expected. Intervention was most urgently necessary in cases of laryngeal tuberculosis. The operation was a simple one and involved little or no tax upon the woman. With the exception of certain localized processes, tuberculosis was likely to prove a serious complication of pregnancy. In a large proportion of cases the disease took on a more active course in the later months and especially was this true of the puerperium. Lactation was also recognized as a danger period, but this could be eliminated. The tuberculous woman was not permitted to nurse. Termination of the pregnancy in the later months, with the exception of certain grave complications of the disease, or when demanded in the interest of the child, was, as a rule, useless. It was believed by many authorities that premature labor was not so well borne as spontaneous labor at term. There was, however, a wide difference of opinion on the question of therapeutic abortion in tuberculous women. Nearly half the recent writers were opposed to it at any period and under any conditions. While admitting the pernicious influence of the disease they denied that it was retarded by abortion. In looking over his histories Dr. Jewett said he was surprised at the comparatively small number of cases of pregnancy with tuberculosis that had fallen under his care, and he reported three cases occurring within the year. While he recognized the difficulty of formulating rules for all cases he thought that, in most instances, at least of beginning tuberculosis, the interest of the mother would best be served by terminating the pregnancy in the first three months.

Dr. J. Clifton Edgar said he did not believe that such a large collection of cases had ever been reported as occurring in the experience of one person; Bossi said that he had only been called upon to face this question twenty

times regarding intervention in pregnancy. There seemed to have been quite a difference of opinion as to what course to pursue in these cases. Pinard in Paris observed spontaneous resolution of the tuberculosis during pregnancy. On the other hand Lancereaux claimed that non-hereditary cases of tuberculosis had developed as the result of pregnancy and the lowered vitality which occurred with it. It seemed to Dr. Edgar that Pinard's statement was in line with the superstition and tradition that existed, that pregnancy had a tendency to better the condition of the tuberculous woman. The latent or cured or directly hereditary cases of tuberculosis were more liable to suffer from the effects of pregnancy than the non-tuberculous. Two-thirds of the cases of incipient tuberculosis could be cured by proper environment and proper hygiene; therefore, why not treat the pregnant cases as one would the non-pregnant? Dr. Edgar said that he had always taken the stand that pregnancy complicating tuberculosis was a threat or menace. He dissented with the statement that interference with pregnancy in advanced states of tuberculosis was contraindicated, and he reported two cases to uphold this view. It was a good plan to give an easier labor by cutting off one or two weeks of gestation. The labor itself should be made as easy as possible by shortening the second stage with the forceps and by the use of anesthesia combined with oxygen.

Dr. Edwin B. Cragin said that for several years he had taught that it was best to take the radical ground advocated by Dr. Trembley, so far as tuberculosis and early pregnancy was concerned. If there was an active tuberculous process, pregnancy should be terminated at once. There were a certain number of cases in the later months of pregnancy where, in the interest of the mother, the life of the child should be sacrificed; he said he had seen such cases in which the women were going down hill rapidly, and where the additional discomfort of increased pressure and increased disturbance of respiration because of the enlarged size of the abdomen was apparently sapping the life of the women. At the same time, he believed that all were bound to meet with surprises and find that some women with the tuberculosis arrested perhaps, would go safely through their pregnancy in spite of the fact that they had been advised against doing so. Many cases would be much benefited by inducing labor a little early, as at eight and one-half months, thus lessening the severity of the labor by having a smaller child. While in the early months of pregnancy he made no exception to the advisability of inducing therapeutic abortion in active tuberculosis, in the later months one must use judgment.

Dr. James A. Miller said he believed Dr. Trembley's position was a perfectly tenable one. The patient who went through with pregnancy was probably going through the hardest kind of work; therefore, pregnancy should be interrupted at the earliest possible moment in all cases not able to stand such work. There were two classes of cases regarding which it was difficult to make up one's mind as to what course to pursue. First, the early cases that were apparently cured; with these cases he thought it would be much safer and better to wait even longer than one year, as recommended by Dr. Trembley, before allowing pregnancy to occur. Second, those cases which were advanced but had become arrested for a time varying from two, three, six or even eight years. There were cases in which the lesions were very advanced and which gave marked signs in the chest and yet might go without symptoms for years. It was perfectly safe to allow such cases to go to term. However, the only basis they could use in guiding them was, what were the patients able to do? What was the measure of their resistance? With regard to tuberculin, when this agent was used the patients were much less liable to have relapses and they were more liable to be able to take up the routine strain of daily life.

Dr. H. N. Vineberg said he was surprised at the radical attitude taken by Dr. Trembley and reported cases in which harm and not good was done by emptying the uterus in cases of tuberculosis complicated by pregnancy. Another case was reported in which non-interference was followed by good results.

Dr. Brainerd Hunt Whitbeck thought that they should consider more the outlook for the child born of tuberculous parents, especially the advanced cases. The chances of a child born of a mother with advanced tuberculosis developing tuberculosis was comparatively large.

Dr. S. M. Brickner said that it was often surprising the manner in which a tuberculous woman would go through pregnancy, and suffer no reaction whatever, and he reported such a case. He offered a suggestion, based upon a purely theoretical assumption, that during pregnancy the thyroid gland increased in size, and it seemed possible that the secretion which was poured out during pregnancy had an inhibitive effect upon the development of tuberculosis during pregnancy; but this effect ceased during the puerperium and the pulmonary disease, therefore, was allowed to proceed with its ravages. It might be well to give thyroid extract, beginning its use at the ninth month of pregnancy. A point first suggested by Brown and based upon the theory that labor was the equivalent of tremendous manual work which caused an outbreak of tuberculosis, called for delivery at or near full term. After dilating the cervix sufficiently, forceps should be applied and labor terminated as rapidly as possible in order to save the woman as much physical work as possible. Dr. Brickner was opposed to this procedure because in primiparous women it was a hazardous undertaking, while in the multiparous woman the second stage of labor was usually short and not so much physical work was involved to cause an increase in the pulmonary disease.

Dr. William S. Stone said that one of the best papers upon this subject had been written by von Rosthorn, who did not take the radical position of Dr. Trembley. It was possible to individualize in a certain number of these cases; for example, in those cases which had had evidence of a mild process prior to the pregnancy, or in those cases in which the symptoms at present showed a condition that was localized within a small pumonary area; in other words, the decision should depend upon the careful examination made by a medical man rather than an obstetrician. The laryngeal cases were notably the worst type. The cases with hemorrhages were often not the worst ones. v. Rosthorn thought that it was very important to do everything possible to render the labor easy; the extra exertion of labor, particularly the extra respiratory efforts, had a very deleterious influence. Therefore, the suggestion made of bringing the labor on one or two weeks early seemed to be worthy of consideration.

Dr Trembley closed the discussion. He believed that in suitable cases, those who took the tuberculin treatment were less liable to have relapses than those who did not take it. The only way to arrive at a definite conclusion was to have an expression from both the obstetricians and the physiologists, because they looked at this subject from different points of view.

Study of Medicine in Far East.—The objection shown by the Court at Pekin to accept the aid of European surgeons during the illness of China's late rulers does not seem to be shared by the people of Hanoi in Indo-China. Here it seems that the French have established with considerable success a school of medicine. There are ninety students enrolled, some studying the science from the human standpoint, some qualifying as veterinary surgeons, while a number of young women have entered as obstetric students. One lady who has qualified has been signally successful in charge of a hospital for the poor at Phuly. Eight out of ten of the students come from Cochin-China.—*London Globe*

THE CAMMIDGE REACTION IN DISEASES OF THE PANCREAS.*

BY FRANCIS P. KINNICUTT, M.D.,

NEW YORK.

PROFESSOR OF CLINICAL MEDICINE IN THE COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY, NEW YORK.

THE "pancreatic test or reaction," as is well-known, is based upon Cammidge's[1] studies of the urine in disease of the pancreas. The studies indicate, Cammidge believes, that in inflammatory lesions of this organ there is excreted by the kidneys a substance which, on hydrolysis, yields a body giving the reactions of a pentose, and that such a substance is, as a rule, not found in lesions of other organs. The pentosazone precipitate which he obtains by a somewhat elaborate, though easily mastered, technique, consists of golden yellow crystals, exceedingly fine and hairlike in form, arranged in sheaves and rosettes. They are to be distinguished from glucosazone crystals by their appearance under the microscope, their ready solubility in 33 per cent. sulphuric acid and their melting point—about 160 C. To them Cammidge has given the name of "pancreatic reaction crystals," and he believes that their presence in the urine, *i.e.* a positive "pancreatic reaction," is "strongly suggestive of inflammatory disease of the pancreas." During the past 15 months Cammidge's pancreatic test has been applied in all cases of suspected pancreatic disease, of cholelithiasis, of cholecystitis, and of diabetes, admitted to my wards in the Presbyterian Hospital. A table has been prepared giving the results obtained in all cases in the hospital in which the test has been employed. It includes a number of miscellaneous diseases and the findings in a few urinary specimens from individuals presumably healthy.

A study of the clinical histories of the cases giving a positive reaction elicits the following facts:

Although the clinical histories in Cases 1 and 2 were those of cholelithiasis, the diagnosis could not be confirmed in the absence of operation or autopsy. In Cases 3 and 4 a stone was found in the common duct in one at operation—the pancreas is not mentioned; in the second a calculus was found in the common duct, ½ cm. from the ampulla; at autopsy also a chronic pancreatitis, a suppurative cholangitis and hepatitis.

Two of the five cases of diabetes came to autopsy. In one of them there was a widespread hyaline degeneration of the islands of Langerhans and an increase of interstitial tissue. In the second there was fibrosis of the islands of Langerhans and a chronic interstitial pancreatitis. In the case of carcinoma of the pancreas a chronic pancreatitis was also found at autopsy. In the two cases of acute hemorrhagic pancreatitis the diagnosis was confirmed at operation; one of these recovered.

CAMMIDGE'S "C PANCREATIC REACTION"

TOTAL NUMBER OF CASES, FIFTY ONE

Cases	Diagnosis	No.	Positive	Negative
1– 2	Cholelithiasis	2	2	
3– 4	Cholelithiasis and cholecystitis	2	2	
5– 9	Diabetes	5	5	
10	Carcinoma of pancreas with chronic pancreatitis	1	1	
11 12	Acute pancreatitis	2	2	
13	Nepro-lithiasis not confirmed at autopsy	1	1	
		13	13	

Total Cases, 13
Positive Reactions, 13

Cases	Diagnosis	No.	Positive	Negative
1–5	Cholelithiasis	5	0	5
6–13	Cholecystitis	8	0	8
14	Suppurative peripancreatitis, cholelithiasis, cholecystitis	1	0	1
15	Tumor of head of pancreas, of doubtful character	1	0	1
16–17	Diabetes	2	0	2
18	Cholangitis	1	0	1
19–21	Hepatic cirrhosis	3	0	3
22	Perforating duodenal ulcer	1	0	1
23	Gastric ulcer	1	0	1
24	Neurasthenia	1	0	1
25	Intestinal obstruction	1	0	1
26 27	Exophthalmic goitre	2	0	2
28	Vesical calculus	1	0	1
29	Pyonephrosis	1	0	1
30	Chronic endocarditis	1	0	1
31	Chronic portal thrombosis	1	0	1
32–34	Undiagnosed	3	0	3
35–38	Normal	4	0	4
		38	0	38

Total Cases, 38.
Negative Reactions, 38.

In Case 13 the clinical diagnosis was nepholithiasis; at operation no stone was present in the kidney (left) or in the portion of the ureter explored. In the clinical history the pain is described as being present in the back and just below the left costal arch, not radiating. There was no blood in the urine macroscopically or microscopically. The case did not come under my personal observation, but the supposition of the existence of a pancreatic lithiasis, with an associated chronic pancreatitis, should be entertained.

In the thirteen cases giving positive reactions, an inflammatory lesion of the pancreas was *demonstrated* at autopsy in four; in two, at operation (Cases 11 and 12). In two of the thirteen cases gallstones were found in the common duct, one being associated with chronic pancreatitis; the condition of the pancreas at operation in the second case is not stated.

The details of the study of the 38 cases giving negative reactions are as follows:

In Cases 1 and 2 the diagnosis of cholelithiasis could not be confirmed in the absence of operation

*Read at a meeting of the Surgical Section of the New York Academy of Medicine March 5, 1909, Discussion on Acute and Chronic Pancreatitis

or autopsy. In Cases 3, 4, and 5 a cholelithiasis was found at operation; in one of these a single calculus was present in the common duct and one in the hepatic duct; the condition of the pancreas is not stated. In the second case a single large calculus was found in the gall bladder; the ducts and pancreas are stated to have been normal. In the third, a suppurative cholecystitis was associated with the cholelithiasis. The gall bladder contained much thick pus and many stones; the condition of the ducts and pancreas is not stated. There were eight cases in which a clinical diagnosis of cholecystitis was made. Five occurred in the course of typhoid fever and recovered without operation. In the sixth case of cholecystitis the gall-bladder was palpable; recovery without operation. In Case 12 there were no stones in the gall-bladder or ducts at operation; the head of the pancreas is stated to have been indurated. In Case 13 the gall-bladder and all ducts were free from stones; the statement in regard to the pancreas is that it was "rather hard." A case of great interest (No. 14), and the only one among those giving a negative reaction in which a lesion of the pancreas was demonstrated at autopsy, was an acute suppurative peripancreatis associated with cholecystitis and cholelithiasis. Extensive interstitial changes also were found in the pancreas at autopsy. Dr. Opie regards the case as primarily one of acute hæmorrhagic pancreatitis. There was a single case (No. 15) of tumor of the head of the pancreas, of doubtful nature in the absence of autopsy. In Case 18 the pancreas was found to be normal at autopsy. The diagnoses in the remaining cases are given in the table.

In the thirty-four cases giving negative reactions, two came to autopsy, and an inflammatory lesion of the pancreas was demonstrated in one of these; in the second the pancreas was found to be normal. In the remaining four of the thirty-eight cases the urine tested was from individuals presumably healthy.

Cammidge's[2] latest report on the "pancreatic reaction" is to the effect that in 800 specimens of urine examined by his method there was found evidence of disease of the pancreas in all cases where a positive reaction was obtained, and it was possible subsequently to examine the condition of the gland. A positive reaction was never observed either with a normal urine or in any case in which it was not probable that there was some pancreatic "mischief."

Cammidge's findings in eighty-three specimens of urine from forty-eight cases of diabetes are of interest. In thirty-six cases (75 per cent.) there was a positive reaction, suggestive, as he believes, of their pancreatic origin. In twelve cases the reaction was negative. Four of them came to autopsy. In one the pancreas was found to be normal both macroscopically and microscopically; in two the pancreas was stated to be normal, and in the fourth case the gland was not examined.

The cases of diabetes studied in the Presbyterian Hospital series are too few to be of value. The percentage (71) of positive reactions closely corresponds with that observed by Cammidge. Cecil,[7] in his recent exhaustive study of ninety cases of diabetes mellitus, found anatomical lesions of the pancreas in 88 per cent.

Watson,[3] in a late paper on "The Clinical Value of the Pancreatic Reaction in the Urine, Based on Over 250 Analyses," gives a variety of diseases in which he obtained a positive reaction, but in his conclusion states that "if certain facts," which he relates, "are kept in view, and this urinary reaction is carefully studied along with other clinical features of a case," he is convinced that Cammidge's test will prove of great value in the diagnosis of pancreatic disease.

Schroeder's[4] conclusions, based upon a study of 85 cases in which 110 chemical analyses were made, are as follows:

"1. It has been proved that inflammatory and destructive diseases of the pancreas may give rise to the appearance of certain, as yet undefined, bodies in the urine, belonging possibly to the sugars or related compounds.

"2. The reaction is not pathognomonic for disease of the pancreas, in the clinical sense. Extensive clinical observations on the urine in pancreatic and other diseases must finally determine the value of the pancreatic reaction."

Goodman,[5] in a paper of February, 1909, gives the results of the study of sixty-two cases of various abdominal diseases and disorders, including four cases of *experimental* pancreatitis, one of acute pancreatitis, two of chronic pancreatitis, one of carcinoma of the pancreas, one of carcinoma of the stomach and pancreas, four of cholecystitis, two of cholelithiasis, fourteen of diabetes, and ten of cirrhosis of the liver. His conclusions are that the test is of much value and "marks a decided advance in the diagnosis of pancreatic disease."

Eloesses,[6] in an exhaustive study of diseases of the pancreas, largely from Czerny's Clinic, reports the findings in the urine in sixteen cases where Cammidge's test was employed. The diagnoses were confirmed at operation or autopsy. Positive reactions were obtained in four cases of chronic pancreatitis, in two of carcinoma of the pancreas, in one of cancer of the gall-bladder with metastases in the pancreas, in one case of cholelithiasis (stone in the common duct) associated with a pancreatitis, in one of cholelithiasis (stone in the gall-bladder), in one of cholelithiasis, the site of the calculus not stated; in one of carcinoma of the stomach with metatases in the liver; in one case of sarcoma of the retroperitoneal glands the reaction was positive to the earlier Cammidge tests, known as "A" and "B" tests, but which have now been discarded by Cammidge. Negative results were obtained in one case of hepatic cirrhosis and in one case in which the clinical diagnosis was pancreatitis. At autopsy, however, a carcinoma of the intestine was found; the pancreas was normal. Negative reactions were also observed in two cases of dilated stomach.

Turning from clinical to experimental evidence of the value of the "pancreatic reaction," the literature contains the studies of the urine in experimental pancreatitis, by Eichler,[8] Sailer, Speese and Goodman. Eichler's conclusions, based upon positive reactions, obtained from the urine in three cases of acute pancreatitis artificially produced in dogs, are open to the objection of a possibly faulty technique. Sailer and Speece,[9] Speece and Goodman,[10] employing Cammidge's improved C. test, obtained results which, while not conclusive, are highly suggestive of the value of the "pancreatic reaction."

In conclusion, a review of the studies, to the present date, of the urine both in clinical and experimental pancreatic disease, indicates that, while the "pancreatic reaction" is not pathognomonic of, it is strongly suggestive of inflammatory and destructive lesions of the pancreas, and is of much assistance in diagnosis in association with other clinical evidence of disease of this organ.

It gives me pleasure to express my indebtedness to Dr. Meakins and his assistants in the laboratory, and to Dr. Lamb, for their cooperation in the study and assistance in the preparation of the tables.

THE RATIONAL TREATMENT OF TABES DORSALIS IN RELATION TO ITS PATHOGENESIS.*

By TOM. A. WILLIAMS, M.R., C.M., Edin.

WASHINGTON, D. C.

Empirical treatment may succeed in curing disease when the factors are quite simple. Conspicuous examples are found in the curing of malaria by quinine, of secondary syphilis by mercury, and in a certain degree, the amelioration of tuberculosis by out-door life in a good climate; but many a patient has been made most uncomfortable by quinine, syphilitics have been seriously injured by mercury, and it is notorious that consumptives have often failed to receive benefit from life in the open air. All of us now know that these drawbacks and failures were due to a lack of understanding of the precise relationship of the remedy we were employing to counteract the cause of the patient's disorder.

It is to such lack of knowledge that must be attributed many failures in the treatment of tabes dorsalis by mercury. Now that the syphilitic nature of the tabetic process is beyond question, therapeutists are again inquiring why mercury failed in the past, and whether it cannot succeed in the present and future.

To comprehend the issue the pathogenesis of tables dorsalis must be understood. Nageotte's researches [1] showed as early as 1894 a constancy of lesions in the radicular nerve at the point where it receives its meningeal sheaths. These lesions correspond to one or other stage of the granulomatous process, varying as they do from simple round-cell infiltration to granuloma, and even breaking down with formation of cavities. They are due to primary chronic meningitis, evidenced by the lymphocytosis found on spinal puncture during life, and post mortem when skilfully looked for, although the tendency of the process to resolution and fibrous tissue formation leaves only a slight thickening in the membrane already fibrous by nature.[2]

The changes in the cord are consecutive to this. That this is so is proved by similar changes of the posterior column after disease or experimental section of individual roots, and by the change occurring in the mechanical affections of the radicular nerves,[3] due to the increased intraspinal pressure caused by the growth of cerebral tumors.

The noxa falls upon the root fasciculi very disparately; and this corresponds to the disparate nature of the sensory troubles [2] which do not preponderate so much as formerly supposed upon the fibers which subserve the sense of attitudes and of muscular movement. Moreover, Roux [4] has shown that degenerations of the sympathetic fibers always occur in tabes, and that these are quite homologous with the degenerations produced by experimental section of the spinal roots as well as by central destruction of the intermediolateral column.[5]

The chronic meningitis responsible for the disease of the posterior roots and the consecutive degeneration of the posterior columns of the cord implicates also the anterior roots which, however, may effectively regenerate, while the posterior roots can do so only as far as their entry into the spinal cord at Obersteiner's ring where they no longer possess a neurilemma sheath.[6] Hence the sensory loss persists, while the motor loss often recovers. When severed, however, cicatrization of the lesion prevents the passage of the regenerating fibers, and a muscular atrophy persists; and indeed 20 per cent. of tabetics present muscular atrophies, as recent clinical observations have shown.[7]

The Argyle-Robertson pupil and the lymphocytoses of the cerebrospinal fluid are strong evidences of syphilis.[8] The latter is found in the secondary stage in 40 per cent. of cases,[9] and irritations of the nerves which pierce the meninges are not uncommon in this late secondary stage, and may even occur during the roseola. More careful investigation is now revealing a syphilitic etiology of many a neuralgia and palsy, more especially of the sciatic nerve [10] and of the face.[11] Now these are usually quickly removed by mercury in whatever way administered; but in the tertiary stage the therapy is less certain.[12] It would seem that the resistance of the host is impaired, sometimes to the point of hopelessness, as in dementia paralytica, which is now conclusively shown by the Wassermann[13] test to be syphilitic and not parasyphilitic. It is to other causes, therefore, than the nature of the noxa that we must ascribe the failure until now of specific therapy. I believe these are mainly three: (1) Faulty methods of administration; (2) hasty generalization, and (3) overexpectation.

To give mercury by inunction is to give it in uncertain doses, and to make it inconvenient and often annoying for the patient; and this does not conduce to a psychical attitude which favors an immunizing process.[14] Salivation and insufficient dose are equally undesirable. When given through the mouth, not only is its absorption uncertain, but that of food is interfered with, and nutrition must suffer. It is only by inserting mercury directly into the body in known quantities that we can commensurately antidote the noxa of syphilis with the minimum of injury to the patient's tissues. Hence, it is only by this method that it is fair to judge the specific therapy of tabes and paresis; and recent results have justified the hopefulness of the scientific pharmacologist with respect to this, for numerous cases and cures are being reported.[15]

Now do not misunderstand this statement. Recollect that no one expects a cured consumptive to grow a new lung, for destroyed lung tissue is replaced by cicatrix; the phthisis is, however, cured,

*Read by invitation before the Tri-State Medical Association at Charleston, S. C., February 17, 1909.

although the patient's breathing may continue more or less embarrassed. Similarly with the tabetic, although sclerosis cannot be substituted by nerve fibers, yet the tabes may cease by an arrest of the inflammation which has caused it. The locomotor ataxia, however, due to the destruction of certain nerve paths, will be recovered from only in so far as the patient retains sufficient nerve paths to re-educate. Muscular atrophies of long duration will probably persist, for impenetrable scars are probably present. Trophic changes in joints, ligaments, muscles, and skin, in so far as they are secondary to root-nerve degenerations, will remain in *statu quo ante*. But the invasion of the inflammatory process will cease; the patient is recovered, though not restored. If he has been allowed to proceed to the pitch of incapacity, he may be compared to a case in which the papilloedema produced by intracranial tumor has continued long enough to cause blindness before the intervention of the surgeon has been invoked, however successfully, to remove the neoplasm. The patient is cured, though blind. As much may be said for the recovered consumptive incapacitated by dyspnea.

The moral of the foregoing is the imperative need of early diagnosis of the sometimes fleeting and obscure neuralgia, vertigo, mictional, and gastric difficulties, etc., which so often precede locomotor symptoms of tabes dorsalis. A careful neurological diagnosis, sometimes including examination of cerebrospinal fluid, would enable us to anticipate many a locomotor ataxia. Of course, the Wassermann reaction will enable us to dispense with much neurodiagnostic lore and skill; but the installation for this is very complicated, and therefore not available except in certain large centers; and in any case, a certain knowledge of neurological signs is required before one can even suspect an incipient tabes or paresis.

Noguchi[16] has recently discovered a very simple reaction of the cerebrospinal fluid, which he believes to be pathognomonic, of dementia paralytica at least. I have no experience with the method, but it is certain that if it will reveal paresis, it will reveal tabes equally well. Noguchi claims that his test succeeds in a larger percentage than that depending upon the Bordet-Gengout principle. It is as follows: To 0.1 c.c. of spinal fluid in a tube of not over 1 cm. diameter, add 0.5 c.c. of 10 per cent. butyric acid; heat till bubbling, and while hot add 1 c.c. of 4 per cent. sodium hydrate solution. The paretic fluid, in a few moments, becomes flocculent, whereas, normal fluids are only opalescent or cloudy, the flocculence does not depend upon the quantity of the cloudiness, but is characteristic of metasyphilis.

When the diagnosis is made, the manner of treatment outlined will remove from the radicular nerves the infiltrations and exudates caused by the lues. If intervention is early, absorbtion occurs without cicatrix; and the lost conductivity of the nerve fibers, which always precedes destruction, is quickly restored. The invasion of other regions is forestalled, and the general health of the patient is improved.

Time lacks to insist upon the accessory, though essential, hygienic and dietetic factors of successful treatment; but they cannot be too strongly insisted upon. I give all my patients a dietary and an elastic time table by which to regulate their day; and I prescribe their exercise, in order that this essential metabolic regulizer may be procured without undue fatigue.

It would seem inevitable that if this treatment can arrest the tabetic process, it should not fail to put an end to the inflammatory invasion which determines dementia paralytica; for it is clear that the two processes are etiologically and pathogenically the same, differing only in locality. The future will show whether this expectation is realizable in practice. It would seem that the problem is one of diagnosis, early enough to anticipate the loss of resistance due to the massive invasion of the encephalon in paresis.

In this diagnosis, as well as in the prognosis, psychometric methods are of great assistance, as will be shown by cases I shall report elsewhere.[17] Some pathologists will reply to this belief by calling the cases which recover cerebral syphilis, diffuse, arteriosclerotic or gummatous; but the research of Ladame[18] has shown the impossibility of drawing the histotological line between diffuse syphilis and paresis. Moreover, neurological surgeons know how resistant are gummata of the brain to antiluetic treatment; while syphilitic arteritis is irremediable after sclerosis has occurred. So that the therapeutic difference does not seem very distinct; and we must fall back upon the unequivocal evidence of the serum reaction, which declares that paresis is syphilis, and as such must be amenable to a specific therapy, as I maintain. We have only to find the pharmacodynamic way; and it is in order to appeal to the practical trials which will eventuate in a precise method *secundum artem* that I seize the agreeable duty of presenting, as I see them, the main trends of progress in the effective therapeusis of the hitherto hopeless Frascatorian encephalitic and spinal meningitides.

Hospital Practice vs. Private Practice.—According to Gee, the main advantage of hospital practice is the opportunity it affords for examining the bodies of patients after death; while the main advantage of private practice is that you know so much more of your patients during life than you can ever discover about hospital patients, who are only transient.

THE THREE URETERAL ISTHMUSES.

By BYRON ROBINSON, B.S., M.D.,

CHICAGO.

PROFESSOR OF GYNECOLOGY AND DISEASES OF THE ABDOMINAL VISCERA IN THE CHICAGO COLLEGE OF MEDICINE AND SURGERY, IN AFFILIATION WITH VALPARAISO UNIVERSITY—CONSULTING SURGEON TO MARY THOMPSON HOSPITAL.

In the present blooming of ureteral therapeusis, both medical and surgical, it may be well to pause to consider some of the simple but fundamental matters in regard to the ureter. During the past dozen years I have devoted special attention to the *form* of the ureter in animals and man, examining 800. I injected about two hundred ureters of man and animals with air, fluids, liquid paraffin (for corrosion anatomy), red lead and starch. Many were x-rayed. The result of the above investigations is that the human ureter possesses practically three constant uretral constrictions and three constant ureteral expansions. For practical reference I termed these constrictions and expansions the three *ureteral isthmuses* and the three *ureteral dilatations*. The object of this paper is to present the utility of our knowledge in regard to the three *ureteral isthmuses* in the practice of medicine.

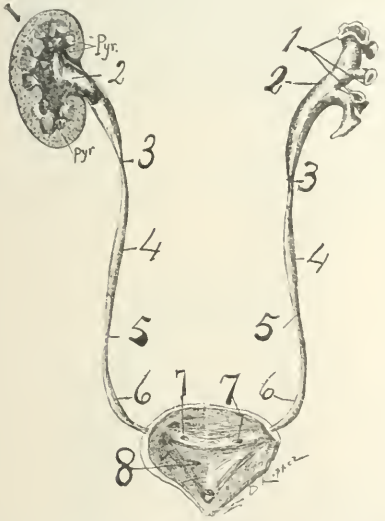

Fig. 1.—The three ureteral isthmuses; the three ureteral dilatations, and the normal course of the ureters; pr, renal pyramids. 1, ureteral calyces; 2, ureteral pelvis (proximal ureteral dilatation); 3, proximal ureteral isthmus; 4, middle ureteral dilatation (lumbar spindle); 5, middle ureteral isthmus; 6, pelvic ureteral dilatation (pelvic spindle); 7, distal ureteral isthmus; 8, trigone. This illustration is a composite drawing of several hundred ureters.

The Three Ureteral Isthmuses (marked 3, 5 and 7 in the figures).—What I termed years ago the three ureteral isthmuses are of the first and foremost importance in the practice of urology. They are the most important landmarks in the ureter. The human ureter presents practically three constant ureteral isthmuses. These ureteral isthmuses or sphincters are periodically rhythmically, functionating structures which allow the intermittent passage of quantities of urine. The erect attitude tells man's story of ureteral isthmuses. The ureteral isthmuses are of both hereditary and mechanical origin, due to the medial projection of the distal renal pole flexing the ureter, the ventral projection of the iliac vessels flexing the ureter on the pelvic margin in the erect attitude, and the obstructing of the urine by the bladder wall. The ureteral isthmuses, so far as their mechanical origin is involved, are due to flexion, angulation of the ureter by adjacent structures. Besides the sphincterial structure of the bladder, the powerful periureteral sheath separating the ureter and bladder and vesical valve aids in perpetuating the three constant ureteral isthmuses. The three ureteral isthmuses marked by primal agencies (kidney pole, iliac vessels, sphincterial bladder wall) are practically constant. In caliber the proximal ureteral isthmus is the minimum, the middle is the maximum, and the distal ureteral isthmus is the medium. The three ureteral isthmuses are significantly important anatomically, physiologically and pathologicall (Besides the three major ureteral isthmuses minor indistinct ureteral isthmuses may exist which possess no special anatomical, physiological, clinical or pathological signification.) The middle and distal ureteral isthmuses possess an age relation due to blood supply from the utero-ovarian artery, while the proximal ureteral isthmuses possess no age relation. The most important factors in ureteral obstruction (or hydroureter) are these three ureteral isthmuses—proximal, middle and distal. They are significant as regards obstruction by calculus or flexion, angulation, torsion. The ureteral isthmuses possess thicker and more powerful walls of fibrous, muscular and elastic tissue than the other ureteral segments. In diseases of the ureters as ureteritis, the three chief points of tenderness on pressure are located at these isthmuses. The three ureteral isthmuses cause the three ureteral dilatations—proximal, middle and distal. The ureteral isthmus are subject to flexion, torsion, ureteritis, hydroureter, stricture, tuberculosis, calculus, malignancy, obstruction by débris, blood clot.

The Proximal Ureteral Isthmus (marked 3 in figures).—This is located at the junction of the pelvic and lumbar ureteral segments, adjacent to the distal renal pole. It is the narrowest point of the ureter. It is the ureteral neck or proximal ureteral constriction. It is the proximal sphincter of the ureter. It is due to angulation or flexion of the ureter by the distal renal pole. In many ureters the proximal ureteral isthmus is fixed firmly to the distal renal pole by connective tissue and may lie in a renal groove, hence it flexes with the movements of the distal renal pole. It may become constricted in renal rotation or renal torsion. Important ideas are associated with the proximal ureteral isthmus, viz., (*a*) It corresponds to the elbow-shaped curve of the ureter adjacent to the distal renal pole. I shall call this proximal ureteral flexure or curve—*flexura renisurcteris*. (*b*) The ureter (calyces and pelvis) is extensively dilated proximal to the proximal ureteral isthmus. (*c*) The lumen of the proximal ureteral isthmus is considerably narrower than the adjacent proximal or distal ureteral portions. On account of the erect attitude of man the proximal ureteral isthmus varies in its distance from the distal renal pole ($1\frac{1}{2}$ to 3 inches). It possesses abundant connective tissue, is a powerful thick-walled isthmus averaging 1/12 of an inch in diameter. It is situated at the junction of the ureteral pelvis and ureter proper. Perhaps 60 per cent. of all calculi lodge at the proximal ureteral isthmus and its flexion or torsion is the chief factor in producing hydroureter (of the ureteral calyces and pelvis).

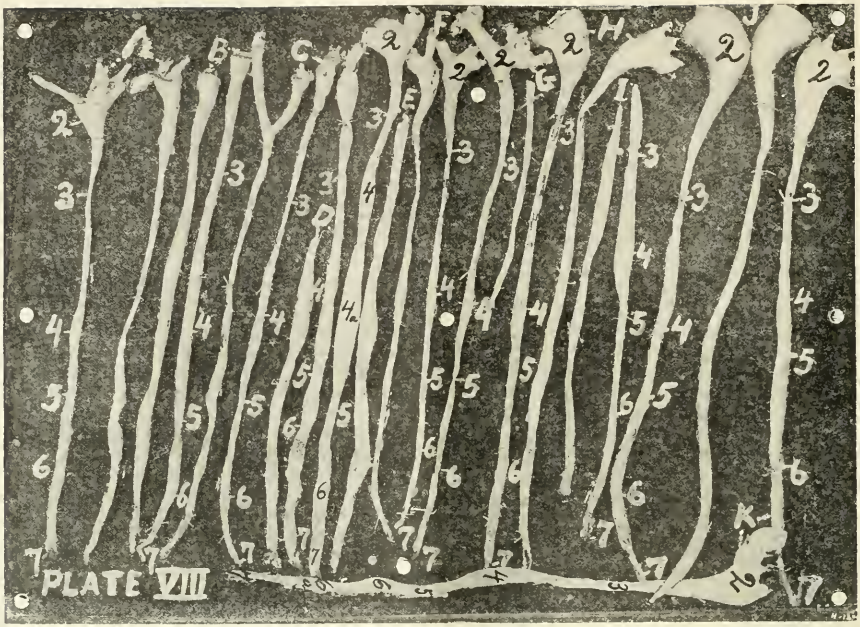

FIG. 2.—Paraffin distended ureters, demonstrating the isthmuses (and dilatations) in 21 human ureters and 1 from a beaver. These ureters I secured in consecutive autopsies without selection. They demonstrate the extensive range of variation in caliber of both ureteral isthmuses and ureteral dilatations. A represents the right and left ureters of a man middle age; B represents right and left ureters of man of 37 years; C exposes the right (partially duplicate) and the left ureter of a man 75 years of age; D shows right (minus pelvis and calyces) and left ureters of man 28 years; E presents right and left (minus pelvis and calyces) ureters of man of 55 years; F indicates the right and left ureters of man of 46 years; G illustrates right ureter of man, unknown age; it also shows a segment of a beaver's ureter (minus pelvis and calyces) presenting constrictions and dilatations; H illustrates the right and left ureters of man of 65 years; I right and left ureters (minus pelvis and calyces) of a woman of 31 years; J right and left ureters of man of 58 years; K right and left (lying at the foot of the picture) ureters of man of 58 years.

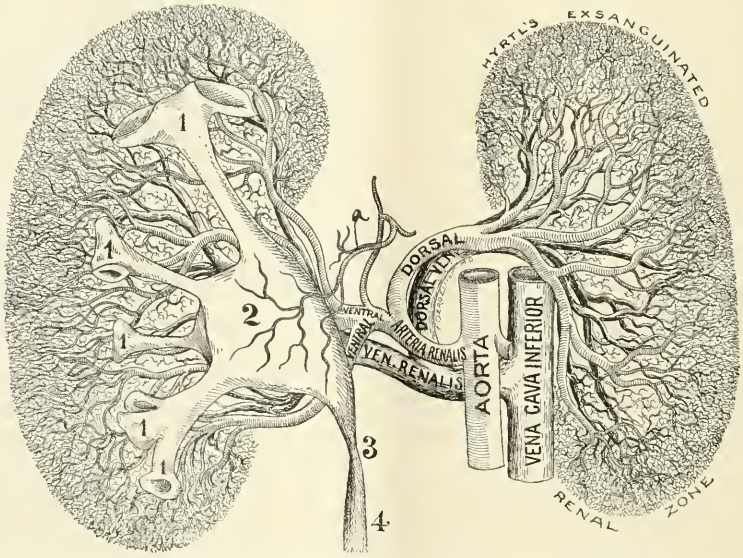

FIG. 3.—Corrosion specimen. The ureteral and renal vascular specimen was injected with liquid paraffin and corroded with HNO_3 for 4 weeks. The specimen represents the renal vascular blades opened like a book, and on the ventral blade like a picture on a page, lies the ureteral calyces and pelvis. This specimen presents quite faithfully the circulation, the kidney, calyces ,and pelvis. The two renal vascular blades are opened like a book. The corrosion was on the left kidney and the larger vascular blade is the ventral one. The vasomotor nerves accompanying the urinary tract may be estimated by the fact that a rich plexiform net-work of nerves ensheaths the arteries, the calyces, pelvis and ureter proper. When the renal vascular blades are shut like a book their thin edges come in contact, but do not anastomose. The edges of the vascular blades are what I term the exsanguinated renal zone of Hyrti, who discovered it in 1868, and we, at present, employ it for incising the kidney to gain entrance to the interior of the calyces and pelvis with minimum hemorrhage. The proximal ureteral isthmus marked 3 is distinct. (The proximal ureteral dilatations marked 1 and 2 are evident.)

Obstruction, flexion, torsion at the proximal ureteral isthmus produce what I have termed the "swan-shaped" ureter (*i.e.*, dilatation of the ureteral calyces and pelvis in the form of the neck and body of a swan), not infrequently found in autopsy. The proximal ureteral isthmus is practically constant for all ages and sexes in erect animals. It offers a slightly increased resistance to the introduction of the ureteral catheter. It may be a point or an inch in length. The malinsertion of the proximal ureteral isthmus in the ureteral pelvis is the cause of considerable dilatation of the ureteral pelvis and calyces, offering mechanicophysiological obstruction to the evacuation of the calyces and pelvis. The proximal ureteral isthmus is the most significant of all ureteral isthmuses. It is the greatest ureteral *landmark* (which is a point for consideration—anatomical, physiological and pathological). Its thick fibrous wall, lack of elastic and muscular tissue and diminutive lumen tell the story of the most dominant point of ureteral obstruction. On account of the greater length of the *vasa renalia dextra*, endowing the right kidney with extensive range of motion and the consequent frequent opportunity of the right proximal ureteral isthmus to flexion or torsion enforces the dominating ureteral obstruction, hydroureter (of calyces and pelvis) on the right. In ureteral obstructions, hydroureter, the proximal ureterial isthmus does not dilate in proportion to other ureteral segments (the ureteral dilatations or spindles). The proximal ureteral isthmus enhances the dimension of the proximal

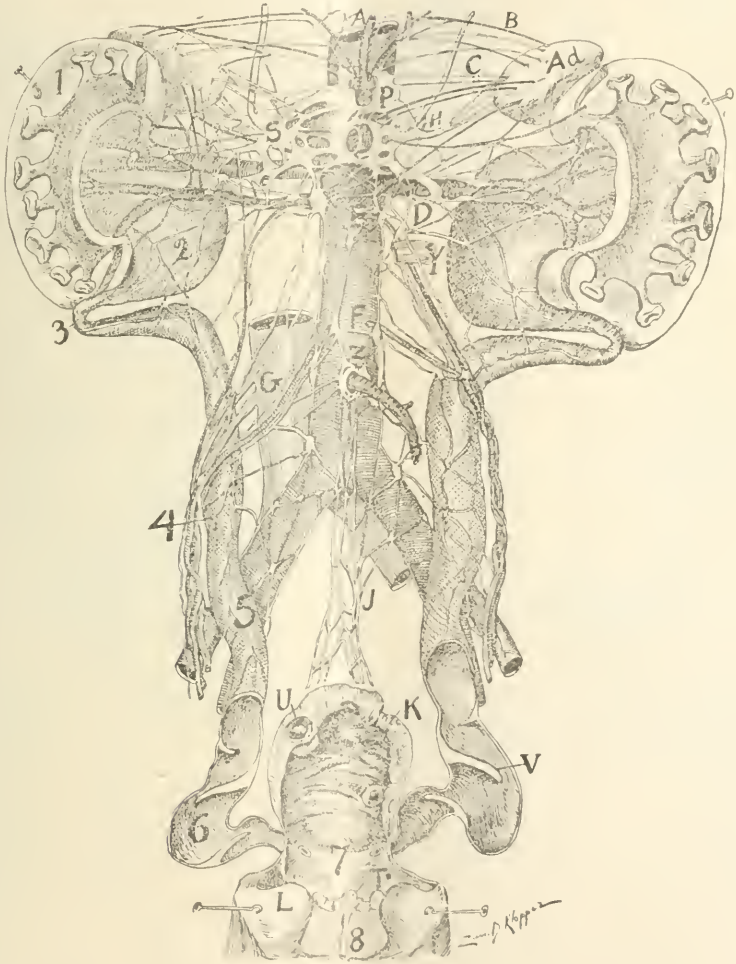

FIG. 4.—This specimen was secured at an autopsy and was drawn under alcohol from nature. It is what I term the "swan-shaped" ureter, i.e. the ureteral pelvis dilates in the shape of the neck and body of a swan. The most indelible impression secured from this specimen is the persistent nondilatable proximal ureteral isthmus (3); the middle isthmus (5) yields the most among the 3 isthmuses; the 3 ureteral dilatations (1-2, 4, 6) are marked, especially 1 and 2; the ureteral pelvis is dilated relatively more than the calyces. The proximal ureteral isthmus was firmly fixed by connective tissue in distinct renal grooves on the distal renal pole. Note the ureteral valves at V. This specimen is accompanied by the vasomotor (sympathetic) nerve, which ensheaths vessels and ducts, ruling their peristalsis. The arteria renalis presents duplicity. From this specimen it is evident that the adrenals and kidney receive enormous nerve supply from abdominal brain.

ureteral dilatation (calyces and pelvis). To demonstrate the proximal ureteral isthmus one need only free the ureter by dissection during surgical procedure or autopsy, but especially distend the ureter with air or fluid or prepare it by injection of liquid paraffin for corrosion anatomy, whence it is indeli-

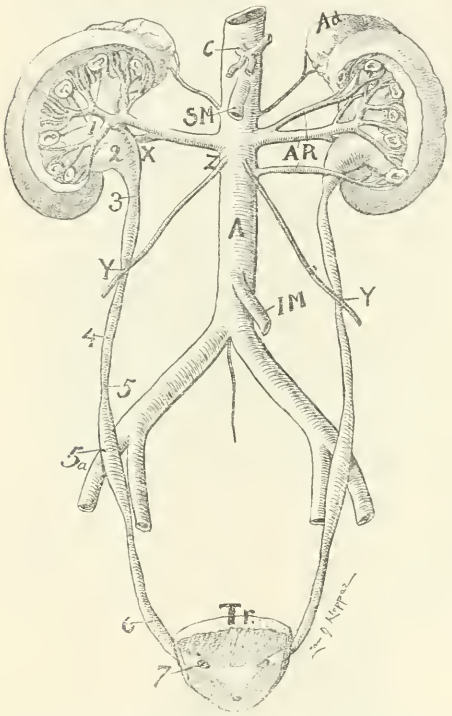

Fig. 5.—This specimen I secured from an autopsy and carefully injected ureters and vessels. I then dissected it and Dr. Klopper drew it exactly from nature. The middle isthmus (5) may not always be located exactly on the iliac vessels as in this figure; the dilated ureteral spindle (5a) occupies the ureteroiliac crossing. The right accessory renal vessel crosses the right ureter on the proximal side of the right proximal ureteral isthmus, which exposes to the danger of hydroureter due to compression.

bly microscopically evident. There can be but slight doubt that many surgeons, unfamiliar with the form of the ureter, have not infrequently mistaken the normal proximal ureteral isthmus for a pathological ureteral stricture. During the distalward or ventralward movements of the kidney by torsion or flexion of the kidney the proximal ureteral isthmus is liable to potential flexion or torsion (periodic) potential hydroureter. During ureteritis the edema or hypertrophic condition of the mucosa of the proximal ureteral isthmus is liable to cause partial or complete obstruction to the urinary stream, inducing gradual or rapid distention of the proximal ureteral dilatation. The proximal ureteral isthmus produces the proximal ureteral dilatation (calyces and pelvis). The proximal ureteral isthmus is subject to flexion, torsion, calculus, ureteritis, catarrh, tuberculosis, obstruction by debris, blood clots, malignancy.

The Middle Ureteral Isthmus (marked 5 in figures).—This is located at the point where the ureter crosses the *vasa iliaca communia*. It averages 1/7 of an inch in diameter and obstructs relatively few ureteral calculi. There is a distinct flexion or angulation of the ureter in erect animals where it crosses the common iliac vessels. The middle ureteral isthmus I shall term *flexura iliaca ureteris*. The middle ureteral isthmus is the middle ureteral sphincter or constriction and is relatively thick-walled, consequently it dilates in proportion less in ureteral obstruction, hydroureter, than the adjacent proximal (lumbar) and distal (pelvic) dilatation. The middle ureteral isthmus is a secondary landmark in ureteral isthmuses. It is nourished by an artery from the iliac vessel. It has an age relation due to the supply from the uteroovarian artery. The middle ureteral isthmus offers a slightly increased obstruction to the introduction of the ureteral catheter. The right middle ureteral isthmus crosses the *arteria iliaca externa*. The left middle ureteral isthmus crosses the *arteria iliaca communis*. The middle ureteral isthmus is the most accessible point of the ureter for palpation, being in the region of the sacroiliac joint. The middle ureteral isthmus causes the middle ureteral dilatation.

The middle ureteral isthmus is subject to calculus, catarrh, ureteritis, tuberculosis, obstruction by débris, blood clot, malignancy.

The Distal Ureteral Isthmus (marked 7 in the figures).—This is located at the point where the ureter traverses the urinary vesical wall. Possessing liberal connective tissue it is a powerful thick-walled isthmus, averaging one-tenth of an inch in diameter. It is the second significant ureteral isth

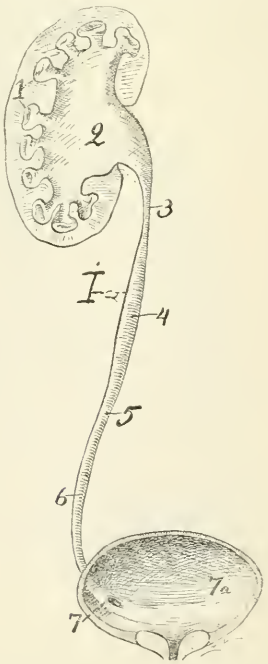

Fig. 6.—This specimen represents the right kidney, ureter, and bladder from a subject possessing no left kidney or ureter. The kidney is 30 per cent. hypertrophied (vicariously assuming the work of both kidneys). The vigorous labor devolving on one kidney and ureter has accentuated the three ureteral isthmuses (3, 5, 7) and the three ureteral dilatations (1-2, 4, 6). Extrarenal function, *i.e.* especially extraureteral peristalsis, accentuates the pronounced form of the ureter, *i.e.* it increases the ureteral dilatations.

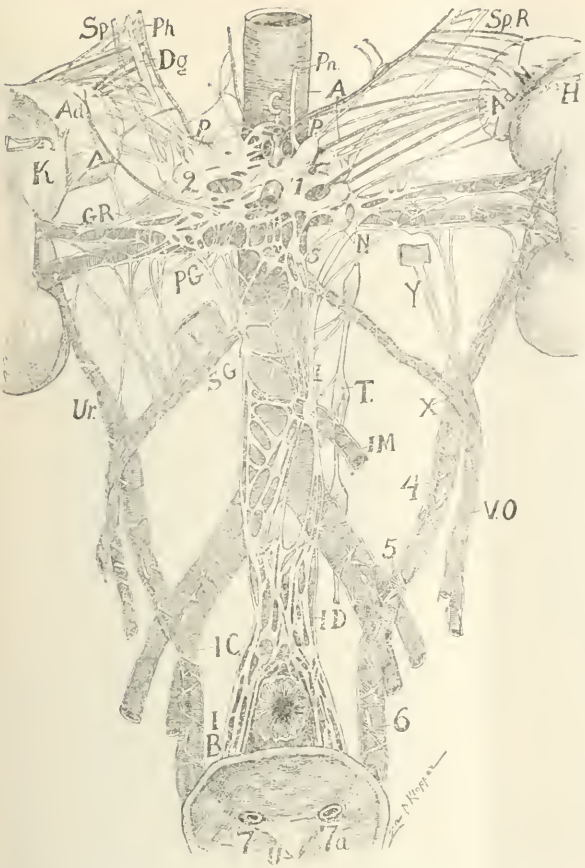

FIG. 7.—This illustration, drawn from nature, illustrates slightly marked ureteral isthmuses (and dilatations). The vasomotor (sympathetic) nerve is pronounced, showing the abdominal brain and vasomotor nerve ensheathing the vessels and ducts. The ureteral isthmuses are located at the distal renal pole, uretroiliac crossing, and the entrance of the bladder; the isthmuses and dilatations are more marked on the right. Note the right proximal ureteral isthmus lodged in a renal groove. The lumbar and pelvic ureteral spindles are marked.

mus. It obstructs many ureteral calculi for considerable periods of time. It is a primary ureteral landmark—anatomical, physiological, pathological—among ureteral isthmuses. The distal ureteral isthmus is a primary ureteral sphincter, a physiological and anatomical constriction. It is located at the lateral angle of the vesical trigone at the base of the bladder. Its thick, fibrous walls, lack of elastic and muscular tissue induce it to dilate less in proportion than its proximally adjacent pelvic ureteral reservoir (pelvic ureteral spindle). The distal end of the ureter is independent, separated from the urinary vesical wall by a cylindrical wall of connective tissue, allowing ureter and bladder wall to functionate independently. The distal ureteral isthmus traverses the urinary vesical wall for three-fourths of an inch, constituting an automatic vascular apparatus—a sphincter or valve of wonderful utility. Normally, no regurgitation of fluids can occur from the bladder into the ureter as the greater the vesical pressure or distention the more firmly are the valves of the distal ureteral isthmus coapted. The distal ureteral isthmus causes the distal ureteral dilatation. It offers slightly increased resistance to the introduced catheter. During ureteritis the mucosa of the distal ureteral isthmus becomes edematous, hypertrophic, and offers partial obstruction to the urinary stream—enhancing the distention of the distal ureteral dilatation. During ureteritis the distal ureteral isthmus may spasmodically and violently grasp the introduced ureteral catheter, offering marked resistance to its withdrawal, and so firmly as to resemble an inverted cone projecting into the bladder. The distal ureteral isthmus is abundantly supplied with blood, hence when obstructed by a calculus it presents remarkable phenomena of hyperemia, edema, eversion, hypertrophy. The distal ureteral isthmus possesses an age relation due to abundant blood supply from the arteria uterina. The distal ureteral isthmus may be safely dilated to evacuate calculus or for other ureteral therapeusis. The distal ureteral isthmus is subject to calculus, ureteritis, tuberculosis, stricture, obstruction by débris, blood clot.

Conclusions.—There exist practically three constant ureteral isthmuses.

The ureteral isthmuses are due to the erect attitude and consequent flexion, angulation of the ureters by adjacent structures (distal renal pole, iliac vessels, and bladder wall—sphincter).

The ureteral isthmuses constitute the most important ureteral landmarks (a landmark is a point for consideration, anatomical, physiological, pathological).

The ureteral isthmuses are points where special ureteral pathology prevails, *e.g.* ureteral flexion, torsion, hydroureter, obstruction by calculus, ureteral stricture, ureteritis, catarrh, hypertrophy of ureteral mucosa, tuberculosis, malignancy, obstruction by débris, or blood clot.

The ureteral isthmuses, because of the presence there of an abundant amount of connective tissue and lack of muscular tissue, dilate less in proportion than the other ureteral segments in ureteral expansion.

The ureteral isthmuses are practically ureteral sphincters.

The ureteral isthmuses are significant in ureteral pathology and are the greatest of ureteral landmarks.

The ureteral isthmuses are significant in ureteral diagnosis.

In ureteritis the ureteral isthmuses represent the tender points of the ureter on pressure. They are also the points where the introduced catheter is obstructed.

In the operation for removing a calculus which is lodged at any one of the ureteral isthmuses, the stone should be pushed forward until it enters one of the ureteral dilatations where the lumen is sufficiently wide to allow for surgical manipulation and for coaptation.

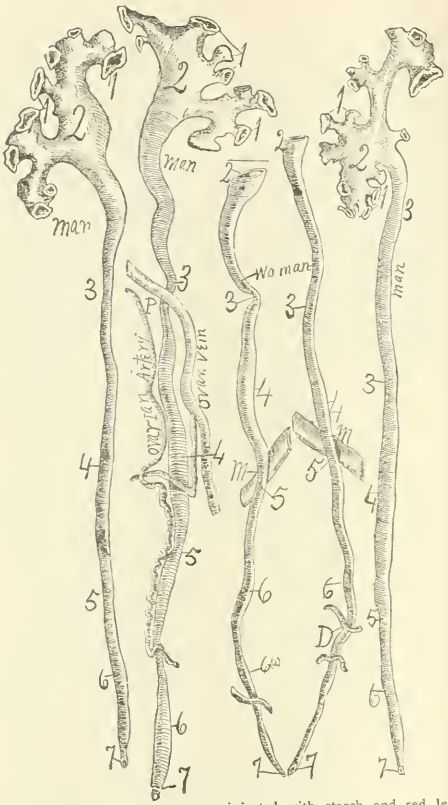

Fig. 8.—These ureters were injected with starch and red lead and *x*-rayed. The ureteral isthmuses (3, 5, 7) and ureteral dilatations (1-2, 4, 6) are evident . Five ureters, half-life size, three with and two without calyces and pelvis. The spindles are obvious, especially those of the woman at 4 and 6. There frequently exist two pelvic spindles, 6 and 6a.

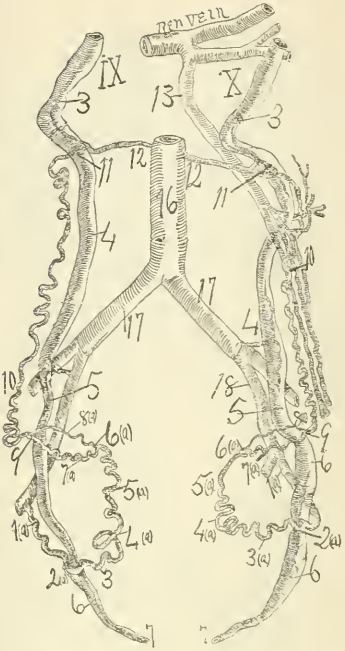

Fig. 10.—This specimen I removed from the body with its associated relations and topography. It was then injected and *x*-rayed. It demonstrates excellently the 3 T-shaped ureteric arteries that supply the ureter. I have named the three ureteral arteries: (1) the ureterica proximalis (at 11), emitted from the proximal end of the ovarian; (2) the arteria ureterica medialis (at 4 and 5), emitted from the iliac; (3) the arteria ureterica distalis (at 2a), emitted from the uterine as it crosses the ureter, *i.e.* at the arteriouteral crossing. The uteroovarian artery being an artery of age or functional relations it imposes by means of its branches an age or function relation on the ureter. Of the branches of the T-shaped uterine arteries one passes proximalward and the other distalward on the ureter. The proximal (11) and distal (2a) ureteric arteries supply the middle and distal ureteral dilatations—hence, menstruation and gestation congest them and senile atrophy cause anemia. The middle ureteric artery (at 4 and 5), being from the iliacs, possesses no age relation. The uteroovarian artery (marked 1a, 2a, 3, 4a, 5a, 6a, 7a, 8a, 9, 10, 11, 12) is shown as to its relations to the ureteral isthmuses and dilatations.

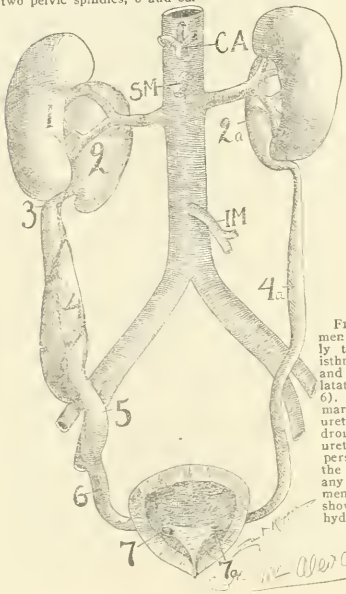

Fig. 9.—This specimen presents markedly the three ureteral isthmuses (3, 5, 7) and three ureteral dilatations (1-2, 4 and 6). Observe that in marked pathological ureteral changes (hydroureter) the three ureteral isthmuses persist, presenting the least changes of any ureteral segment. This specimen shows a right-sided hydroureter.

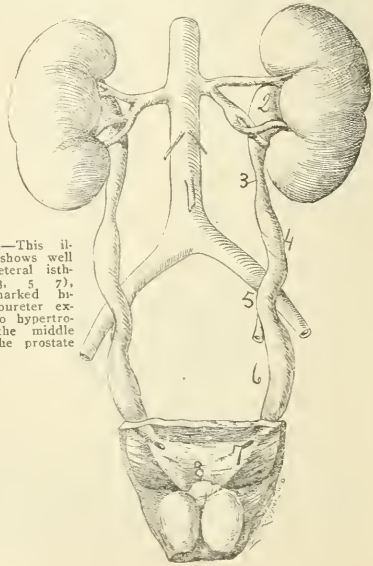

Fig. 11.—This illustration shows well the 3 ureteral isthmuses (3, 5 7), though marked bilateral uroureter exists due to hypertrophy of the middle lobe of the prostate (8).

THE PROPER TEACHING OF THERAPEUTICS IN MEDICAL SCHOOLS.*

By GEORGE F. BUTLER, M.D.,

CHICAGO.

PROFESSOR AND HEAD OF DEPARTMENT OF THERAPEUTICS AND PROFESSOR OF PREVENTIVE AND CLINICAL MEDICINE, CHICAGO COLLEGE OF MEDICINE AND SURGERY (MEDICAL DEPARTMENT OF VALPARAISO COLLEGE).

In the way of introduction to my paper I will say that it affords me great pleasure to note the renewed interest which is being taken in therapeutics, for I believe that our ultimate concern, as a profession, is the prevention and cure of disease. The therapeutic art is the final goal to which the training of the medical student should be directed. As Jacobi recently said: "We live in the era of therapy; therapy in political, social and individual life."

I have maintained for years that the best way to do away with nostrums is to give our medical students thorough courses in materia medica, medical pharmacy, pharmacology, and therapeutics. The way to abolish proprietary medicines is to teach medical students how to prescribe, and acquaint them with the physiological and therapeutic action of drugs. They should be taught how to write or compound prescriptions that would be palatable and agreeable, compatible yet so associated or combined as to meet the indications for which the prescription is intended, in a scientific manner.

If our medical students were able to do this there would be fewer therapeutic nihilists; secret remedies would be relegated to antiquity and it would mark the beginning of the end of sectarian schools of medicine. But how is it now? There are some colleges that do not teach materia medica and therapeutics at all, and there are many State examining boards that do not examine on these subjects. The average medical student comes out of college to-day with very little knowledge of these branches. He goes to the bedside ignorant of these matters and not knowing the action, uses, or, in many instances, the doses of drugs, and not knowing how to write a prescription, he naturally falls back on some proprietary medicine. Is it any wonder that the people use "patent medicines" and patronize quacks? Physicians themselves are to blame for the discredit which the lay press casts on the medical profession, not only because of their ignorance and scepticism regarding the value of drugs, but because of the bitter controversies among themselves.

There are in our ranks therapeutic nihilists, and therapeutic anthusiasts, and their discussions over non-essentials have retarded our progress in therapeutics. At the best, as Gregg says, "our advance has been rather by slow and patient endeavor and calm and deferred judgment—Line upon line, precept upon precept, here a little and there a little." So have we climbed and so must we continue to plod along our way. The history of medicine is full of the announcements of cures and systems of cures that have, in most instances, been relegated to the rubbish heap by the test of time. After all, we have few, if any, specifics. The practice of medicine is still difficult and often times discouraging, but our best therapeutic friends are, perhaps, after all, the old time-honored drugs.

So-called nonmedicinal therapeutics has a place and a large one, and I shall say a few words on this subject later, but agents of this class can never entirely replace drugs in the treatment of disease.

*Read before the Physicians' Club of Chicago, Friday, November 27, 1908.

It is our duty to seek a happy medium between therapeutic nihilism and polypharmacy, and ever to study the principles that govern the rational treatment of disease.

Our aim, as teachers of therapeutics, should be to make it, if possible, a science as well as an art, to teach rational rather than empirical methods, and to trace the relations between therapeutics and biology. We must confess, however, that we are still far from being able to explain the principles of much of our treatment; a great deal of our drug treatment is still empirical, but the rational increases every day, and much of the old empirical disappears. While the modern physician is dissatisfied and should be dissatisfied with empiricism, we cannot as yet abandon all our empirical methods. We know as did our ancestors two hundred years ago that mercury is good treatment for syphilis, but we understand little more than they in what way it acts. We believe that salicylates are useful in acute articular rheumatism, and we guess at the secret of their efficiency. We speak of certain drugs as "specific" for certain diseases, meaning thereby that they seldom fail to produce good effects, but of the infinite number of steps between the administration of the drug and the beneficial result we know next to nothing. While I impress upon my students the importance of knowing why and how of therapeutic action, and not be satisfied, as is the empiricist, with the fact, I do not go so far as to advise them not to use one of these old, well-tried "specifics," salicylates for example, because they cannot explain how it acts. It was not so very long ago that we were ignorant of the action of quinine in malaria, but we knew that it seldom failed to alleviate the symptoms of the disease.

Our students should be taught rational, scientific therapeutics so far as we understand it, but we should avoid "over-training" them, otherwise we will turn out ultrascientific men—men with the materialistic and sceptical spirit so developed that they are devoid of all reason and common-sense—utterly incapable of properly treating a sick human being, yet perhaps thoroughly familiar with the action of diethyl-sulphon—diethyl-methane on the blood of a healthy mongrel bitch. Which leads me up to my subject which is "The Proper Teaching of Therapeutics in Medical Schools." I wish to amend this by striking out the work "proper;" I think it is a *good* method and offer it for what it is worth.

Recently there have been so many self-constituted "authorities" who have advocated this and that remedy and method of treatment or no treatment at all, with so much assertive intolerance, that I am wearied with anything that smacks of "authority."

In the college with which I am connected as head of the department of therapeutics, drug therapy is taught as follows: During the first semester of the freshman year the students are taught, by lectures, recitations, and laboratory work, the appearance, physical properties, official name, English name, synonyms, botanical source, active constitutents, and official preparations of the vegetable official drugs. Important unofficial drugs are also considered. In connection with this, the student also learns methods of administration, and the doses of drugs and preparations. Four hours a week are devoted to this work.

Most of the second semester of the freshman year is devoted to work in pharmacy. It embraces the principles of metrology, and the various processes used in the manufacture of chemicals and

pharmaceuticals. It also includes a study of the various classes of preparations, such as waters, solutions, fluid extracts, tinctures, plasters, pills, powders, wafers, etc. The didactic work is supplemented by demonstrations and exercises in the laboratory. The elementary principles of prescription writing are also taught during this course.

It is also explained to the student in this course what is meant by assayed or standardized drugs. Standardization was a great advance toward accuracy in therapeutics as it gives us preparations of more or less uniformity. Yet, after all, standardization is merely a step in the evolution of an exact and definite materia medica.

Standardized preparations when made by the same pharmacist are not always uniform in strength, and I will add for fear of being misunderstood, that alkaloids and active principles are not always uniform in strength, and the same influences, such as exposure to air, etc., which cause the deterioration of one class of preparations will deteriorate the other. This entire question of instability in preparations is now regarded by experts as unanswerable except by means of long-continued experiments which are now being carried on.

I impress these facts upon my students and urge upon them the importance of prescribing only the best obtainable preparations, and if, for instance, they find that one house makes a uniformly reliable and active preparation of ergot, if that is the preparation they desire, they should not hesitate to specify this make or any other brand that they find by experience is reliable.

As the matter now stands we are compelled in the majority of instances to make a physiological assay at the bedside, giving enough, regardless of the dose recommended, to produce the desired results.

I bring all these points out to my students, and tell them it is just as important to be sure of the reliability of any drug they give a sick person as it is of the aseptic condition of their hands and instruments in performing an operation. To use cheap, unreliable medicines is criminal negligence.

In the sophomore year pharmacodynamics is taught, together with a review of the properties of drugs, incompatibilities, pharmacy, prescription writing, and therapeutic indications. I urge laboratory work in pharmacology. Much of our prgoress in rational therapeutics is due to experiments upon animals. Not only have many new and valuable drugs been discovered, but serious errors in the use of well-known drugs have been corrected through the observation of their effect on animals. Thus digitalis was at one time recommended for aneurysm, because it slowed the heart, until it was shown by experiments on animals that it not only slowed the heart but raised the blood-pressure.

While considerable work of this kind is done I impress upon by students the fact that pathological conditions very often modify the effects of drugs to a very considerable extent; that the action of drugs is not always the same in disease as in health; that the action of a drug is not necessarily the same on a sick human being as it is on a healthy animal. A drug may or may not possess certain decided action on a healthy, robust bull pup without having any remedial action whatever on a sick baby —or *vice versa*. In other words, pharmacological experiments to be of practical value must be corroborated by the results of clinical experience.

Throughout the entire junior year the therapeutics of drugs by classes are given—as for instance, drugs whose chief action is on the nervous system, drugs acting chiefly on the circulatory system, etc. —in connection with their physiological action, methods of administration, contraindications, untoward actions, and a review of prescription writing are taught. Didactic and clinical lextures are also given on nonmedicinal therapeutics.

In this year I call the attention of the students to the fact that the treatment of the various grave diseases is not altogether a matter of giving drugs, but that other measures are of equal if not in some instances of greater importance; that when midicine is administered in pneumonia, typhoid fever, and many other diseases it is used to relieve the accidents of disease, not to cure the essentials. Here, for the first time, I begin the discussion of the treatment, curative and preventive, of bacterial diseases by vaccines and antitoxins, or, in other words, the treatment of disease by the production of artificial immunity. Time alone can tell whether or not vaccine treatment has a future before it. The gradual improvement of its methods must bring with it a wider applicability to diseased conditions. It in its turn may give place to something better, but for us at present, we must take it as it is, and teach our medical students all that is known about it.

The opsonic method is a long step in the right direction. But there are other diseases than those of microparasitic origin to be overcome, and we have yet to explain the action of drugs and of other therapeutic agents. That drugs do not, in many cases at least, act directly upon the tissues or organs to modify their action or restore their function is evident, yet that they do act in some way is equally evident. That they act by affecting the nervous centers in all cases is also an untenable assumption. We have learned that nature regulates the function of certain organs by means of specific substances, hormones, secreted in one part of the body and carried by the blood to another part, conveying the message that it is time now for that part to act and to do its appointed share in the work of the economy. It is probable that something analogous to this occurs in disease and that drugs are hormones, or stimulants to the production of hormones, conveying the information that something is wrong in a certain part of the economy and calling upon the curative powers of the organism to exert their specific action in that direction. This is the theory advanced and developed by Sajous in his work on "The Internal Secretions"; a theory, which in my opinion gives promise of raising therapeutics more nearly to the rank of a true science than it has yet attained. This seductive theory is fully explained to my students.

In the first and second semesters of the senior year didactic and clinical lectures are given on medicinal and nonmedicinal therapeutics. Students are required to outline a course of treatment for various diseased conditions under the supervision of the professor in charge. This outline includes not only nonmedicinal measures, serums, organic extracts, etc., but the various drugs used in the treatment of the individual, the preparations of the drug most suitable for the particular case, and the scale of dosage. Frequent quizzes and exercises in prescription writing are given during this course.

Preventive medicine is included in my department. As important as a knowledge of therapuetics is it must be admitted that the system of relieving mankind of its misery and load of disease can no

longer rest alone on what is called curative skill. We have entered an era to which the steady effort must be not only to cure, but to prevent disease. In our medical colleges we should endeavor to reconcile the two different systems; to systematize the preventive part of medical science; to bring the preventive part into entire accord with the remedial; in short, to teach our students the inter-relationships which exist between the two parts—remedial and preventive medicine. You will notice that in the college I am connected with therapeutics and preventive medicine are taught throughout the full four-year course.

It may be argued that therapeutics could very well be taught along with medicine. The objection to this is simply that there is not time—that in the subject of medicine there is so much to be done in the way of teaching, etiology, pathology, diagnosis, etc., as well as treatment, that it is impossible to enter into a comprehensive discussion of all preventive and remedial measures.

With my associates and assistants we aim to teach in our college not only medicinal but nonmedicinal therapeutics, such as electrotherapy, radiotherapy, phototherapy, thermotherapy, hydrotherapy, mechanotherapy, massage, dietetics, therapeutic exercise, hygiene, sanitation, climatology, psychotherapy, etc., our aim being to supply a digest of the general principles of *all* valuable therapeutic measures to arrange well-known facts of practice, together with the explanations furnished by pathologic research and physiologic inquiry in such array and form that the student may be a well-informed, useful physician, competent to intelligently and scientifically treat the sick and able to instruct the public in the latest advances of hygienic and sanitary science.

Lately we have devoted considerable time to psychotherapy, for I believe that it is impossible to divorce the psychological from the pathological. Day by day the physician is face to face with appreciable forces that spring up in the heart and brain, and a thorough or working knowledge of psychotherapy is essential nowadays to the successful practice of medicine. "Moral medication belongs to the higher sphere of the doctor's duties, and if he means to cure his patients permanently he cannot afford to neglect them."

Empirical practitioners should not monopolize all the good nonmedicinal measures. We devote much time in the Junior and Senior years to electrotherapy, covering the fundamental principles of electricity—galvanism as used in electrolysis, the electrocautery, the uses of the faradic current and the static or induced current. Special attention is given to the teaching of the proper method of electrolytic medication. There is now plenty of life in ionic therapeutics, for the dry bones of the subject which have long been with us have now begun to live and move. The nature and use of the x-ray, high-frequency currents, leucodescent and other forms of light, and radium are taught.

One of my associates devotes almost his entire time to the teaching of scientific, practical hydrotherapy, and I look forward to the time when our medical colleges will have every facility for teaching all these methods, where therapeutic clinics can be held, and scientific observations made upon the patients.

In conclusion I will add that in my course in therapeutics I try to impress upon the student's mind that a doctor should not look upon each patient as a "case" of this or that "disease," of interest only as the victim of some morbid process furnishing him an opportunity to demonstrate his diagnostic skill; but as a suffering human being, possessing the attributes of humanity collectively, together with some variations which form individual peculiarities, and who should be relieved, if it is in the physician's power to relieve him.

While I try to teach rational, scientific therapeutics, I wish my students to avoid the conceit of the ultrascientific mind and while they remember the words of Huxley that "all true science is such exactly in so far as it strives to pass out of the empirical stage," I do not want them to forget that, after all, "all true science begins with empiricism." We cannot afford to belittle the results of observation and experience. It behooves us all to maintain an attitude of the widest tolerance.

I am desirous of sending out men who are generous, liberal, and broadminded, and original and independent thinkers. And last, but not least by any means, I try to teach my students that there is an ideal as well as a real or material side to the practice of medicine; that in order to be good doctors, and that means good therapeutists as well as good diagnosticians, they not only must thoroughly master the subjects now taught in medical colleges, but they should have high ideals and live up to them, they should not only be scientific, but cheerful, optimistic, and fearless, kind and sympathetic men and women.

DIAGNOSIS AND TREATMENT OF DIABETES MELLITUS.*

By JOHN DUDLEY DUNHAM, A.B., M.D.,

COLUMBUS, OHIO.

PROFESSOR OF DISEASES OF THE STOMACH AND OF DIETETICS, STARLING OHIO MEDICAL COLLEGE.

QUITE frequently during the past five years articles have appeared with titles somewhat as follows: "A Plea for the General Practitioner?" "What is to Become of the General Practitioner?" "The Rôle of the Family Doctor to Send Patients to the Specialists." The thoughts contained in such contributions indicate that many general practitioners feel that their sphere is very rapidly being encroached upon by the specialist. Internal medicine as a specialty has received a large share of this criticism.

What does it all mean? Simply this: Medicine has so far advanced from the stage in which diseases were diagnosed by looking at the patient, his tongue and possibly feeling his pulse, that the public has observed the change. At no distant date the patient will demand that his physician be supplied with the latest scientific knowledge in the diagnosis and treatment of his disease. Moral: The physician must have as his ambition not to be the busiest man in his community and see the greatest number of patients, but must have uppermost in his mind the desire to so study his cases that they will receive the best services that the modern art of medicine can give. This means some laboratory work and much thought given to the preparation of special diet lists for each patient and varying ones for each as the progress of the affection may indicate. In many instances the patient is quite willing to pay for this sort of service in an adequate way. The great majority will more gladly pay for

*Read before the Columbus Academy of Medicine, November, 1907.

this work than for the "jolly" extended with a dozen tablets. To illustrate: About two months ago a patient from Pennsylvania consulted me. Her history was begun with the statement that she was suffering from diabetes and had been given a leaf torn from an old text-book, with directions to cut out all starches and sugars. This advice she had followed for six months. She came to ask if some change could not be made suitable to her own case, for she was getting worse—suffering from manifold nervous disorders, insomnia, thirst, and some skin irritation. Her physician had remarked at the last test of her urine that her progress was satisfactory, as the sugar was reduced; whereas upon examination, diacetic acid and acetone were found. This case is a good example of the effort to cure glycosuria while the patient emaciates and develops a dangerous acidosis.

The general practitioner will come into his own when he makes himself familiar with modern methods of diagnosis and treatment. Few diseases receive as cursory an examination and as careless a treatment as diabetes mellitus. The patient will, in the majority of cases, be better off if let alone than when given opium and have all sugars and starches eliminated from the diet. It is for the purpose of calling attention to a few neglected phases of this subject that I have attempted this paper. "Diabetes may be defined as a disease of impaired metabolism marked by a deficient power of oxidation resulting in the incomplete combustion of carbohydrates and fats of the food and tissues." (F. Stuart Hart, *N. Y. Medical Journal*, Sept. 15, 1906.) More important than the mere presence of sugar in the urine is the excessive amount found in the circulating blood producing a hyperglykemia.

Normally the glucose is oxidized into carbonic acid and water and is so excreted. In diabetes, carbohydrates are not oxidized and in the severe forms the power to oxidize fats is weakened. As a result we have diacetic acid, acetone, and beta-oxybutyric acid formed. In such cases an acidosis is present with the accompanying severe symptoms. Proof has been established that true dyspneic coma is due to the excessive production of beta-oxybutyric acid.

Many classifications of glycosuria have been suggested, but the simplest and most practical is into mild and severe. (1) Mild, embracing those cases in which a limitation of the carbohydrates for three-quarter days will cause a disappearance of the glucose. (2) Severe cases in which an abstinence from carbohydrates for many days will not cause a disappearance of the glucose. In many severe cases limitation of proteids also fails to cause glucose to disappear. Many variations are found; thus, an apparently mild case may prove, after observation, to be severe, and *vice versa*. It must be self-evident to any one who has given the subject the least thought that in almost every case of diabetes there must have been a mild or beginning stage, amenable to treatment. If more care were taken in examination these patients would be saved for years from the severe form of the disease, and, in fact, some would undoubtedly be cured.

The examination of every patient should include urine tests for albumin, casts, glucose, and indican. There is a general idea prevalent that if a urine has a specific gravity of 1,020 or under, no glucose can be present. I have found glucose in five cases in which the urine varied from 1.010 to 1.020. One writer F. Stuart Hart, *loc. cit.*, has observed the same condition in over fifty cases. Allow me to suggest a few instances illustrating how glycosuria may be overlooked. Children who have digestive disturbances should have the urine tested for sugar. Glycosuria occurs much more frequently in children than is usually supposed.

(1) During my service as physician at the children's home some years ago, my attention was called to a boy of 12, against whom a complaint of gluttony had been made. Examination of his urine showed a large amount of glucose. This boy was already in an advanced stage with polyuria, voracious appetite, etc., and died within the year from pulmonary tuberculosis.

(2) A man of 40 years was referred to me by Dr. W. C. Davis. His complaint was a persistent cephalalgia which a correction of an error in his refraction failed to relieve. He also complained of indefinite digestive disorders and occasional diarrhea. Examination of the digestive functions failed to reveal any alterations from the normal. The urine showed a distinct reaction with Fehling's solution. The urine collected for twenty-four hours measured two quarts and contained 2 per cent. glucose, no diacetic acid or acetone. A reduction of carbohydrates caused a cessation of digestive disturbances and headache, with apparent cure.

(3) A specimen of urine was sent me by Dr. D. L. Moore. The patient, aged 33, had advanced seven months in her fourth pregnancy. No albumin was found. Glucose was found in quite an appreciable amount. The Fehling's test was supplemented by the use of the Einhorn saccharometer, on account of the well-known fact that the urine of pregnant women in the later months of pregnancy often gives a positive reaction with Fehling's test when no glucose is present, the reaction being caused by lactose. The patient had noticed no symptoms of diabetes, but when told of the findings thought she had eaten more sweets than usual, had been drinking more water than was her custom, and perhaps was passing more urine. When measured, it was found that 2½ quarts were passed in twenty-four hours, 2 per cent. of glucose was found as were also acetone and diacetic acid. Elimination of carbohydrates from her diet caused a disappearance of glucose only after five days, while the diacetic acid and acetone persisted for some days longer. How frequently is the urine of pregnant women tested for sugar? May it not be that some of the obscure cases of coma and collapse after labor are caused by an acidosis associated with a glycosuria?

The limits and purposes of this paper will not permit a discussion of the theories of etiology. I wish, however, to mention the importance of an hereditary predisposition to the weakness in carbohydrate metabolism. This is very remarkable in the study of the case histories of diabetic patients. An individual whose forebears have suffered from severe neuroses, gout, and diabetes, should be careful in his use of alcoholic drinks and carbohydrates in general, and should submit specimens of urine to his physician for examination at least twice yearly.

The simplest reliable test for glucose in the urine is Fehling's. If the two solutions are kept separately there is no need for renewal, as they will not deteriorate. The precipitation of the red cuprous oxide in this test is not positive evidence of the presence of glucose, as other substances have a similar reducing power. In the performance of this test the least liability to error will be found if the solutions, after being united in equal parts, are diluted

about six times, and the urine diluted four times. The use of the Einhorn saccharometer will settle the question where doubt exists, and at the same time will determine the quantity of glucose excreted. The fermentation test will give positive reactions for levulose and maltose, but as these two bodies are so rarely found the error will be very slight. Quantitative test for glucose should be made only upon a sample of the collected and measured urine for twenty-four hours. In this manner only can one learn the amount of glucose excreted during twenty-four hours, which is the only glucose test of value in treatment. The question arises in cases of glycosuria as to whether its presence is due to transitory causes in the liver—a so-called alimentary glycosuria. This can be ascertained by excluding carbohydrates until the glucose disappears and then, after administering 100 gm. pure glucose, if the urine contains sugar by the ordinary tests, we are justified in speaking of a pathological glycosuria.

Given a patient in whose urine a pathological glycosuria has been demonstrated, one must then ascertain the severity of the disease. The first step before giving any dietary is to collect the total amount of urine for twenty-four hours and find the amount of glucose excreted for this entire time. This may be done by titration of the urine into an accurately measured amount of Fehling's solution, or by using the Einhorn saccharometer or some other fermentation apparatus. If glucose is found by this test in fair amount without the presence of acetone bodies, about to be described, we conclude we have a mild case in which there is weakening of carbohydrate oxidation, but normal fat oxidation. The next step is the test for acetone. For this test the urine must first be distilled. Then Lieben's test may be used. The method is to add to the distillate some Gram's solution and sodium hydrate. If acetone be present in large amount there will occur an immediate precipitation of iodoform. Smaller quantities may be recognized by a microscopic examination of the sediment for crystals of iodoform. Glucose and acetone indicate that in addition to the failure to take care of carbohydrates there is a weakness in the oxidation of fats. Diacetic acid should now be looked for. This test must be carried out with a fresh specimen of the urine. Add a 10 per cent. ferric chloride solution to the urine in a test tube or graduate. A yellowish precipitate of ferric phosphate will form, and the reagent must be added until this disappears entirely; then if diacetic acid is present the further addition of the reagent will show a deep reddish-brown color, the so-called Bordeaux red reaction.

The presence of glucose, acetone, and diacetic acid indicates a severe grade or form of the disease. The most severe forms of diabetes show in the urine the above bodies and also beta-oxybutyric acid.

The final step in diagnosis is the discovery of the degree of oxidation still possible in the metabolism of the patient. In other words, his tolerance for carbohydrates must be estimated.

This is to be done by a test diet which must be weighed. Several authors, Naunyn, von Noorden, and H. Strauss, among others, have suggested special diets for this purpose. Before advising a test diet it is wise to lead gradually to an elimination of the carbohydrates, as failure to do so will often produce an acidosis of grave proportions. The diet suggested by von Noorden is the most nearly ideal and also practical one which may be employed. This diet allows 100 grammes of bread, half given with the breakfast and the other half with the evening meal. After the use of the test diet, the urine should then be collected and tested. If glucose persists the bread must be eliminated. If sugar still remains, we have to do with the severe forms, and a reduction of the proteids must be made. The aim is to ascertain, if possible, the tolerance of the patient. Naunyn demands a stricter dietary than von Noorden. In severe cases he advises starvation except for water for a day or two if the glucose fails to disappear under other measures.

When we have found the degree of tolerance of our patient we must then decide how near the limit we may go with due regard to the patient's general condition and the elimination of diacetic acid and acetone. This is the rock over which we most often stumble.

Very few text-books emphasize sufficiently the necessity of treating the patient and not the glycosuria. A careful searching examination must be made in each case to find the associated or underlying diseases which the patient may have. Syphilis, arteriosclerosis, anemia, etc., must be found if present. Many symptoms, notably diabetic gangrene, are caused by associated conditions and not by the diabetes itself. When the acetone bodies increase while the sugar decreases, it is necessary to add carbohydrates regardless of the patient's tolerance, or diabetic coma is apt to supervene.

Strauss, in his new book on "Diätbehandlung der inneren Krankheiten," gives quite sensible and valuable directions along this line. The diet suggested for the use of diabetics must never be an unlimited one. When we have established the equilibrium of the diabetic the weekly weight record is to be kept rigidly, and estimations of the amount of glucose in twenty-four hours, as well as of the acetone bodies, are to be made regularly. Finally, let me insist that there is no diet for diabetes, as no two patients can use the same amount of carbohydrates. If von Noorden, who has treated upwards of 2,500 cases, has been unable to hand out a stock diet list to his patients, you and I must be satisfied to study each case for itself. I have not discussed drugs because I feel that their use for the limitation of the glycosuria is wrong except in the very advanced and hopeless stages of the disease. Opium and arsenic are recommended as most advantageous. Just as soon as we adopt these medicinal measures we give up any possible hope of raising the tolerance of the diabetic for carbohydrates. While with the dietary treatment the patient's tolerance is often increased. Sodium bicarbonate 50 grs. a day should be used for severe acidosis. The physician may in many cases bring about a condition very closely approaching perfect health if he will give an intelligent consideration to his diabetic patient.

185 East State Street.

Preventive and Curative Treatment of Puerperal Infection by the Use of Essence of Turpentine.—Fabre advocates the use of essence of turpentine both as a preventive of puerperal infection and as a curative treatment when the infection has begun. The preventive treatment is used by injecting equal parts of sterilized water and essence of turpentine into the uterus after labor as a routine treatment. When infection has occurred the same injections are used twice or three times in the twenty-four hours, as long as the infection remains localized in the uterus. When it has become generalized the drug is used by sub-cutaneous injection into the cellular tissues. The results have been excellent, as the treatment has been employed in the Maternity at Lyons.—*L'Obstétrique.*

THE HISTORY OF TUBERCULOSIS.*

By GEORGE FREDERICK LAIDLAW, M.D.,

NEW YORK.

It is a great pleasure to be with you to-day and to take part in this demonstration. The history of tuberculosis is a broad subject. It reaches back to the dawn of medicine. The word phthisis takes us back to Hippocrates, who described clearly the cough, the emaciation, the sweats, the diarrhea, and fatal termination. The word tuberculosis is of more recent origin. It dates from the revival of the study of anatomy by dissection in the sixteenth century. It was the Hollander, Sylvius, who first associated the clinical disease, phthisis, with the formation of nodules in the lungs.

Of the many sides of the tuberculosis question that I might bring before you, I have selected the history of its treatment as most practical. The most significant fact in the history of tuberculosis therapeutics is the turning of all schools of medicine to the ancient doctrine of vitalism. Now, what do I mean by vitalism? I mean that, in tuberculosis, we have stopped trying to kill the bacillus. This is mechanism. We are learning rather to depend more on strengthening the natural resisting forces of the body. In the words of my good friend, Dr. Morris, instead of trying to kill the bacillus ourselves, we back the man in his fight against the bacillus.

Vitalism or the dependence on the patient's vital resistance played a subordinate part in the early history of tuberculosis. The hygienic treatment of phthisis was good, where any was attempted at all, a sea voyage, residence in the pure air of the mountains, and abundant food; but the medical treatment was hopelessly corrupted by the prevailing pathological theories. The chief medicines were expectorants and the so-called antiphthisica, which consisted mostly of the salts of iron, efficacious in checking hemorrhage, but useless to cure the disease.

In the beginning of the nineteenth century the treatment of tuberculous phthisis was aided indirectly by the development of exact physical methods in the exploration of the chest, whereby the physician could recognize the condition much earlier than formerly, with corresponding benefit to the patient.

In the middle of the nineteenth century, however, tuberculosis therapeutics was at a very low ebb, and the hopelessness of the profession was only too often confirmed by the course of the disease. It was at this point that Brehmer, in Silesia, began teaching the curability of phthisis by open air, rest, and food. Brehmer was the founder of the modern sanatorium treatment, and we all owe him a debt of gratitude. It is true that open air and feeding had been used sporadically for centuries; but we owe Brehmer this great debt, that he insisted against much opposition and inertia on the curability of phthisis, and kept on insisting until the profession at last adopted his views.

The year 1882 ushered in the bacteriological era with Robert Koch's masterly work in the discovery of the tubercle bacillus. For a time the profession was bacillus-mad. Timid diagnosticians were afraid and are still afraid to make a diagnosis of pulmonary tuberculosis unless the bacillus was found in the sputum. Recently there has been a welcome reversion to well-tried physical signs, and the physician who now waits for the appearance of the bacilli in the sputum before making a diagnosis of pulmonary tuberculosis is rightly regarded as having waited too long.

Marked as was the effect of Koch's discovery on diagnosis, it was destined to work a still greater revolution in therapeutics; and for the first time the question was squarely presented: Shall the medical treatment of tuberculosis be mechanist or vitalist? Shall we kill the bacillus or stimulate the vitality of the patient?

For a time, it looked as if the mechanist method would triumph, at least in popularity. To the mechanist, killing the bacillus seemed equivalent to curing the disease, and many weird and wonderful methods were devised for this purpose. We had Bergeon's insufflation into the rectum of sulphuretted hydrogen and carbon dioxide, which were exhaled by the lungs and supposed to suffocate the bacilli in transit. Creosote had long been used as an antiphthisicum. It was now believed to kill the bacilli when exhaled in the breath. In the *Journal of the American Medical Association* for 1887, page 143, you will find the formula for a marvellous antiseptic pulmonary lozenge that dissolves in the stomach, is exhaled in the breath, and kills the bacilli en route. Time lacks to review the antibacillary mania in all its vagaries. Suffice it to say that we are past all that. In this antibacillary treatment, the headlong, enthusiastic mechanist did not see what was plain as day to the vitalist, that, even if you should succeed in killing the bacilli, the patient was just as vulnerable as before; that the patient had certain natural protective powers, and, if these were stimulated, he would get well and kill the bacilli himself.

In looking back on the antibacillary days, I perceive one great good which may not have been achieved by any less spectacular method. It impressed the medical mind strongly with the curability of consumption, and however foolish the methods, they have passed away and left as a legacy a firm faith in the curability of consumption which is probably worth all the temporary error.

It is fair to state that in this fantastic bacillus hunt, the homeopathic school as a body did not share. Not that they knew any more about tuberculosis; in fact, from a pathological point of view, they probably knew less; but they have always been vitalists. They have by training an antipathy to interfering by chemical and physical agents with the mechanism of the body. Their method is to stimulate the body tissues to do their own bacillus-killing or any other physiological work that is necessary.

It is fair to state also that Koch and the practical bacteriologists kept aloof from antiseptic pulmonary therapeutics. It was chiefly the work of clinicians untrained in bacteriology, but it was none the less widespread, because so plausible. Koch and the bacteriologists were working along a different line, and with Koch's discovery of the curative power of the extract of the tubercle bacillus, tuberculin, the era of vitalism in bacterial therapeutics fairly opened. Into the history and uses of the various tuberculins I have not time to enter. It is enough to say that, in using them, we are treating a bacillus disease with a substance that is not a germicide, that will never kill the bacillus; but which stimulates the tissues of the body to protect themselves,

*An address delivered at a mass meeting of medical students at the International Tuberculosis Exhibition, American Museum of Natural History, New York, on December 8, 1908.

sets in motion the body's own protective apparatus while the nature of the protective mechanism remains absolutely unknown. A more perfect example of vitalistic therapeutics does not exist.

In the art of medicine, we owe much to the great epidemics. "This is no flattery. These are counsellors that feelingly persuade me what I am." The sciences of hygiene and prophylaxis were born in the great plagues. It was another plague, syphilis, that shattered the Galenic system of pathology and therapeutics, and just so surely is the modern plague, tuberculosis, shattering medical idols of ten generations and leading medical thought to long-neglected vitalism, to the preservation, the care, and the stimulation of the body's own protective power and curative power.

Let me say a word about the dose of tuberculin. Vitalism leads inevitably to the use of the single remedy and the smallest effective dose. The history of all vitalists is alike in this. When Koch found that ten milligrams of tuberculin aggravated the disease, and reduced the dose to five milligrams and then three and one, and then one-tenth of a milligram, he was following step by step the footprints of that other great vitalist of one hundred years ago, Samuel Hahnemann. Professor Wright went further, to one-thousandth of a milligram. Professor Denys has got down to one-millionth of a milligram, and the end is not yet.

These men have been accused of imitating the small doses of the homeopath. Let me, a homeopath, state here that I can claim no such honor, for this my own school. It is not that you are imitating the homeopathic dose or system. It is that you are adopting the vitalistic attitude toward tuberculosis, and vitalism leads inevitably to the single remedy and the smallest effective dose, as, in past centuries, it led Paracelsus, and Sydenham, and Stahl, as it led Hahnemann one hundred years ago, and as it is leading Robert Koch and von Behring and Wright to-day.

This, gentlemen, is my interpretation of the history of tuberculosis.

A TRAY FOR HOLDING INSTRUMENTS DURING SURGICAL OPERATIONS.

By B. F. JENNESS, M.D.,

P. A. SURGEON, U. S. NAVY.

The device illustrated is intended to facilitate the handling, and insure the maintenance of asepsis, of instruments on the operating table.

During surgical operations instruments not in use are usually poised on the mounded surface of the sheet in the region of the patient's chest or abdomen, or are deposited between the thighs, in which situation they sink deeply, carrying the sheet with them. In either resting place they are in a precarious position for the maintenance of asepsis, and their whereabouts is uncertain in time of need.

The patent instrument trays, which are attached to and overhang the table, are not a success and in consequence are now seldom seen in the operating room.

Any operating sheet can be supplied with tray, and to be well equipped it is advisable to have three sheets with a tray on each attached at the level of the chest, abdomen and knees, respectively. This supply of sheets will give a choice of location for the instrument tray, depending upon the field of operation. If only one sheet beside the abdominal one is supplied with the tray, it can be reversed if necessary, thus bringing the tray at the level of the chest or knees. The tray for the abdominal sheet should be attached at the epigastric level in order that it may be well clear of the opening into the field of operation.

The tray consists of a pocket of sheeting 14x10 inches stitched on three sides to the operating sheet,

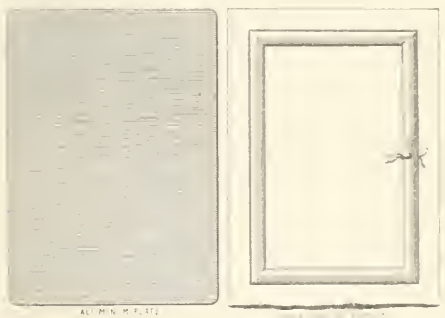

Fig. 1.

at one of the positions mentioned, and equidistant from the sides of the sheet. The open side of the pocket is preferably a short side and the one most convenient to the table upon which sterile dressings, gowns, etc., are deposited from the sterilizer, differing of course in accordance with the accustomed arrangement of the particular operating room in question.

A hem of sheeting of sufficient diameter to carry easily, but snugly, a half-inch rubber tubing is stitched to the pocket, one inch from the seam on three sides of the pocket and from the free edge on the fourth side. This hem now forming a tube of sheeting, will measure 12x8 inches. It will give better service if sewn by hand with strong thread, and is reinforced at the corners by the button-hole stitch. The ends of the tube or hem of sheeting are furnished with short tapes which will tie the approximated ends securely at the top and at the sides. Three tapes on each tube end are necessary.

A piece of firm rubber tubing ½ inch in diameter is now passed through the entire hem. The tube is drawn in about an inch from one end of the hem

Fig. 2.

and allowed to project an equal distance beyond the opposite end. The projecting end of rubber is passed into the empty inch of hem and the tapes are tied.

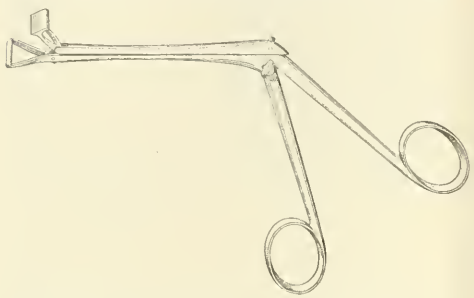
An aluminum plate 13⅞x9⅞ inches in size (Fig. 1), with slightly rounded corners completes the outfit.

The enclosed quadrangle of rubber tubing 12x8 inches, attached to the pocket on the operating sheet, is left as a permanent fixture. The sheet is sterilized as usual, as is also the aluminum plate. When the sheet is placed in position the sterile plate is slipped into the pocket, and the tray is ready for the reception of instruments, sutures, sponges, etc.

A FORCEPS FOR THE REMOVAL OF TAGS, ETC., ON THE POSTERIOR PHARYNGEAL WALL AFTER ADENOID OPERATIONS.

By ALFRED WIENER, M.D.,
NEW YORK.

This forceps can be applied in close proximity to the posterior pharyngeal wall. It cuts and does not tear off the mass to be removed. The blades work scissor-like in action. The edge of the lower blade is serrated, thus preventing the mass, when once within the grasp of the instrument, from being



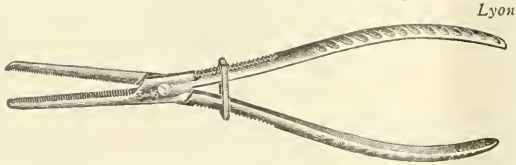
crowded into one corner, or slipping away from the instrument, the fault of so many others. Only one hand is necessary for its manipulation. The other hand is free to depress the tongue, if necessary, thus enabling the operator to obtain a clear view of what he wishes to remove. It is especially adapted for rapid work. The forceps is made by E. B. Meyrowitz, New York.

616 Madison Avenue.

AN IMPROVED HYSTERECTOMY CLAMP.

By HOWARD CRUTCHER, M.D.,
ROSWELL, NEW MEXICO.

In the Medical Record for February 29, 1896, I had the honor to present to the profession a surgical lock, consisting of a steel ring sliding over serrated surfaces, which up to that time had never been employed in surgical practice. The principle was first applied to my hysterectomy clamp, but was afterwards extended to cover other instruments, among them the hemorrhoidal clamp de-



scribed in the Medical Record for September 23, 1905. The only alteration in the present instrument will be found in the handles; this in no wise affects the vital simplicity of the lock. There have been numerous modifications of the blades used, but the simple principle of the steel ring against a saw-tooth surface is, and is likely to remain, unchanged.

My thanks are due to Messrs. Sharp & Smith, of Chicago, for the courtesy of the accompanying illustration.

New Researches on the Etiology of Tetanus. Influence of Hepatic Lesions as Predisposing Factors.—M. H. Vincent says that there are many predisposing causes which render the body a suitable soil for the growth of the tetanus spores. Such are local microbian associations, injury of the tissues by contusions, burns, slight wounds, the action of quinine, hematoma in a wound, hypothermia, insolation, and heat prostration. The author has made animal experiments to demonstrate that tetanus occurs more easily in animals who have some lesion of the liver which renders the hepatic functions subnormal. It has been found that many of the germs become encysted soon after infection in the cells, and that such germs lose their virulence and vitality. But they are not destroyed, and may become virulent at a later period, which explains the sudden appearance of the infection when it is impossible to find the slight wound of entrance. Lesions of the hepetic parenhcyma place the organism in a state of receptivity to the germs. Hence tetanus may be the indirect result of an affection of the liver when the subject carries the spores in his system.—*La Bulletin Médical.*

Globular Resistance of the New-born with Reference to Its Relations with Idiopathic Icterus.—E. Leuret has made a study of the globular resistance of the new-born. He has established the globular resistance in normal babies, and has compared it with that of infants affected with idiopathic icterus. He finds that in icterus the globular resistance is reduced. This condition is only transitory; it does not exist at birth, does not exist in the blood from the umbilical cord, and does not last after the beginning of icterus. It exists only in the preicteric period, coinciding with the yellowing of the skin, the increase in granular corpuscles and plasmochrome, and the emission of highly colored urine. When icterus really exists the globular resistance has returned to normal. Most of these infants with diminished globular resistance have had a subnormal temperature. This appears to be a vital reaction. The blood globules of the fetus, badly adapted to extrauterine life, undergo a rapid hemolysis due to substances set free in the circulation to destroy them. On the contrary, the new formed blood cells, which are adapted to extrauterine life, are more resistant and survive. This hemolysis is a physiological phenomenon. In icterus there is a greater rapidity of globular destruction caused by too great cooling of the body.—*Gazette Hebdomadaire des Sciences Médicales.*

Radicular Brachial Paralysis of Obstetrical Origin.—Louis Gallicadrin and Jean Rebattu describe a case of obstetrical paralysis of some rarity. Such lesions are not very rare, but they generally involve the motor power alone. The upper extremity, arm, and forearm are paralyzed and the fingers are untouched. In the author's case the motor troubles were not marked, the groups of muscles being none of them entirely atrophied, and all movements possible, although with less than normal force. There was entire sensory paralysis, tactile pain, and thermic senses being absent throughout the upper extremity. The patient had burned herself severely, and bore the scars, on account of her inability to feel heat. The symptoms were confined to the portions supplied by the brachial plexus, the posterior roots having been ruptured and the anterior roots only stretched. To cause such a lesion the arm must have been hyperextended while the head was flexed upon the chest and turned to the opposite side.—*Lyons Médical.*

Croup and Morphine.—A. Lesage and Maurice Cléret have made use of morphine in membranous croup to avoid the spasms of strangling. They find that although opium is so poisonous that it should be left out of the theraptutics of infancy it is on account of the other alkaloids contained, and not of the morphine. The last named alkaloid is harmless, and most beneficial in spasm of the larynx. Infants bear its use admirably. It is given to prevent the necessity of intubation whenever the authors find a case of laryngeal stenosis of diphtheritic nature. A dose of one-quarter, one-third or one-half cubic centimeter of a 1 per cent. solution is given according to the age of the infant, and with it an injection of antidiphtheritis serum of 80 to 120 cubic centimeters. In most cases the infant sleeps calmly without spasm for five to six hours and wakes practically cured. Intubation is avoided and a cure results without its inconveniences. In other cases the duration of intubation is lessened and a retubation is avoided. The lesions of the larynx and the complications resulting are lessened in number and severity. The sleep which is given to the child puts him in the best possible condition for resistance.—*La Tribune Médicale.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, April 10, 1909.

A YEAR'S WORK OF THE PUBLIC HEALTH SERVICE.

As a record of good work well done the annual report of Surgeon-General Wyman of the U. S. Public Health and Marine Hospital Service for the fiscal year ended June 30, 1908, is a very interesting document.

The first thirty pages are taken up with an account of the labors of Dr. Blue and his associates of the service in suppressing the outbreak of plague in San Francisco and thereby preventing what might easily have become a widespread and disastrous epidemic of the disease. The country at large has not been slow to recognize its indebtedness to the Marine Hospital Service in this respect, but few probably have any idea of the difficulties encountered in this task. The disease appeared in 1907 and efforts were made by the municipal and State authorities assisted by officers of the service to suppress it, but without success, and in November of that year, five months after the first case was discovered, a telegram was sent to the President requesting the Federal Government to take immediate charge of the beginning epidemic. When the surgeons assigned to the work arrived they found the difficulties apparently almost insuperable. The city was in a period of reconstruction after the fire, the streets were littered with all manner of débris and the people were living in certain sections of the city under most unhygienic conditions. Many were gathered together in temporary camps where the sanitary conditions were of the worst, the shacks were built of scraps of sheet iron and bits of old lumber, the lavatories were open pits, and garbage was scattered about or kept in open wooden boxes. The stables of the city were hastily constructed and insanitary buildings, the grain being kept on the floor or in open bins, and these and numerous chicken yards offered every attraction in the way of shelter and food to rats. Coincident with this there was an unusual prevalence of flies and fleas.

The city was at once divided into districts, each of which was placed in charge of a medical officer with a force of inspectors and assistant inspectors and a gang of laborers employed in rat trapping and poisoning, fumigating and disinfecting. Officers were also detailed to address public meetings on the history, nature, and mode of spread of the disease and on the necessity of getting the entire city as soon as possible in a sanitary condition. In three months the disease was eradicated, the last human case being reported in February, 1908. Plague-infected rats were still found, however, and the campaign against the rodents is even yet being carried on. In reviewing this work, Dr. Wyman insists upon the necessity of a general warfare against rats throughout the world, and especially of their destruction on shipboard. It is questionable, he thinks, how far a war of extermination against rats can be successful in cities, but the animals can be kept out of ships, and if this is done there will be an end to the spread of plague from one seaport to another.

In the field of scientific research and sanitation there has been a gratifying increase in the operations of the service, several new subjects having been taking up in addition to a continuation of the routine work of previous years. The work in this department embraced the following: "Supervision of the manufacture of vaccines, serums, and toxins; investigations in relation to the pharmacopeia; investigations of typhoid fever in interstate traffic; cooperation with the Lake Michigan Water Commission; investigation of rabies, and treatment in the Hygienic Laboratory of persons bitten by rabid animals; studies of hook-worm diseases; studies of pellagra and publication of literature in relation thereto; studies of milk and its relation to the public health; investigations of devices and appliances advertised for the treatment of diseases; investigation of a case of leprosy in Virginia; studies of leprosy at the national leprosy investigation station in the Territory of Hawaii; analyses of drugs, water, and other public health investigations in the Hygienic Laboratory; aid to the International Congress on Tuberculosis; and aid to State and municipal health officers in the determination of specimens, examinations, and analyses of a public health character."

A detailed report is made of the quarantine service, domestic, insular, and foreign, maintained by the surgeons of the bureau, and also of the medical inspection of immigrants to determine their physical fitness for entrance at ports of the United States and its dependencies. Nearly a million immigrants were examined during the fiscal year by fifty-one officers especially detailed for the service.

Special attention is directed by Surgeon-General Wyman to three institutions of the service mentioned in this report, viz., "First, the Fort Stanton (New Mexico) Sanatorium for the reception of tuberculous patients of the service. The results of the open-air treatment are noteworthy, and the service is now reaping some of the benefits of its efforts to sustain this institution in part by the products of the farm and dairy and by the herd of beef cattle. This herd, numbering now some fifteen hundred head, is maintained upon the large range provided by the reservation and supplies the beef necessary for the station. Second, the leprosy investigation station, at Molokai, Hawaiian Islands. The buildings are now about completed, but while

awaiting their construction the director has been engaged in a scientific investigation of the disease, particularly with reference to cases in the first stage before their segregation on the island of Molokai. His reports already show considerable progress in his investigation, and the bureau is encouraged in the belief that this institution will be successful in its legalized quest with regard to leprosy and its treatment. So far as can be ascertained, this institution, established by the liberality of Congress, is the first organized effort of any government to pursue the objects above mentioned continuously until success shall have been achieved. Third, the Hygienic Laboratory, the work of which has been referred to above, has become firmly established as a scientific center of research in regard to contagious and infectious diseases. The personnel of the laboratory numbers, all told, fifty-two, and its recent reports, particularly upon typhoid fever and the relation of milk to the public health, have been recognized, both in the United States and abroad, as standard works on the subjects named." The addition to the laboratory, for which Congress appropriated $75,000, is now in course of construction. Plans were prepared by the Supervising Architect and the work is done under the direction of that office. The completed building will be 230 feet long. This addition will somewhat relieve the congested and crowded condition of the present small structure. The activities of the laboratory, however, have grown so fast that they are believed to have already outgrown the addition. A further addition is needed to provide necessary space for the experimental and routine work and to afford room for the classes of student officers, as well as the lectures and demonstrations which are given to the students of the Naval Medical School and to the Army Medical School, for rabies work, for the lighting and power plant, heating and ventilating apparatus, and, finally, to give proper and comfortable shelter to the animals under experimentation. An item has therefore been included in the estimates to Congress for an appropriation of $175,000 for this purpose. Congress could hardly be asked to give so small an amount for a better purpose.

Only six of the two hundred pages of the report are devoted to Marine Hospitals and Relief, showing strikingly how widely the bureau has departed from its original purpose expressed in the former designation: Marine-Hospital Service. The growth and increase in activity of the service during the past few years have indeed been wonderful. Instead of a small body of medical men treating sick and injured sailors at a few of the larger seaboard and lake ports, we see now a completely organized sanitary service looking after the health interests of the entire country, restricted as yet in its field of usefulness but constantly enlarging this field as more and more authority is given it as a consequence of the awakening of public sentiment regarding sanitary questions and of the recognition of the services rendered the country in times of epidemic. If the time ever comes, and it almost certainly will come, when the public health is deemed of sufficient importance to be looked after by an independent department of the Federal Government, with a cabinet officer at its head, the department will be found already organized in the Public Health and Marine Hospital Service, now only a bureau of the Treasury Department. A still further increase in the work of the service is foreshadowed in a request which President Taft has made of Dr. Wyman to formulate a plan for the consolidation of all the existing government agencies for the guarding of the public health.

In order to maintain the efficiency of the corps and its esprit and to assure that admissions thereto shall be from among the most highly qualified medical candidates, it is essential, Dr. Wyman says, that the compensation, as now fixed by law, be increased to meet the necessities of modern living, these salaries being practically the same as provided twenty years or more ago. This increase is further made necessary because of the increase provided for the medical officers of the army and of the navy and to prevent a consequent disadvantage to the Public Health Service if its officers do not receive compensation equivalent to that given to officers holding analogous positions.

VENOUS ANESTHESIA.

The inventive mind of August Bier has added another technical procedure of apparently great importance to the art of medicine. It is the production of local anesthesia by the introduction of the anesthetic into the veins of an extremity, a method which he presented for the first time last year at the Congress of the German Surgical Society and to which he devotes a comprehensive paper in the *Berliner klinische Wochenschrift* for March 15, 1909.

His experience with simple local anesthesia has shown that the sheaths of nerves offer great resistance to the entrance of an anesthetic, a fact which well explains the difference between the effectiveness of a local anesthetic injected into the tissues and the same drug introduced into the spinal meninges. Lumbar anesthesia, however, has almost as many disadvantages as inhalation narcosis, while local infiltration anesthesia but seldom allows large operations to be performed painlessly if bones or joints as well as soft tissues are involved. Moreover the quantity of the drug used in producing infiltration anesthesia is sometimes large enough to introduce the possibility of dangerous toxic effects.

Venous anesthesia consists in the introduction of the anesthetizing drug into the veins of an extremity which has previously been made as bloodless as possible by tight bandaging; two bandages are used and the drug is introduced into the veins between them. Bier differentiates between "direct" anesthesia produced between the two bandages and "indirect" anesthesia which occurs somewhat later and which robs of sensation all of the limb below the bandages. The individual circumstances of each case determine which method is to be used, the bandages being adjusted either to include the field of operation between them or to have all of it below the lowermost bandage. Using either of

these methods Bier has performed ten amputations, thirty-seven resections, and a great number of smaller operations upon the soft parts, the bones, and the joints of the extremities. Among the total one hundred and thirty-four operations, the anesthesia was unsuccessful in only five cases, three of them occurring in children in whom all local anesthesias are, of course, uncertain procedures. The only possible contraindication Bier sees is in cases of diabetic gangrene, inflammation and gangrene having developed in the amputation stumps of three diabetic subjects after operation under venous anesthesia. It was not improbable, however, that a like result would have occurred in any case.

Bier acknowledges that there is much room for improvement in the anesthetic solutions used by him and in the general technique of the procedure. He seems to have no doubt, however, that this method of producing extensive local anesthesia is the best that has so far been devised.

MEDICAL CLUBS AND THE MEDICAL PROFESSION IN GERMANY.

One of the most illuminating theories of modern historical science is the so-called "economic or materialistic explanation of history" which sees the mainsprings of the actions of large classes of population, not in mental or moral factors, but in the economic circumstances under which these classes fight for their existence. To put it simply, the measures by which men earn their food and drink, determine their attitude in questions of conduct; the ideation of one class, therefore, may be quite different from that of another class of the population, and yet seem to single individuals of each class the only proper and correct way of looking at the world.

The truth of the main contention of this theory of history is well exemplified in a most interesting controversy which is at present going on in Germany between the physicians and the united benevolent associations (*Krankenkassen*). It has been the practice of the latter to engage physicians to look after the health of their members. Only the physicians designated by the societies could be appealed to in case of sickness, and as these associations are very popular in Germany, their directing bodies soon obtained a great deal of power in determining the financial success of individual physicians. The matter progressed so far that finally the whole profession of the land declared itself for the principle of the so-called "free choice of physicians" which would give the members of the benevolent associations the right to select their own physicians who can then collect the regular fee established by the associations. An attempt was then made by the associations to find physicians who would be subservient to their rules, but only seventy physicians were found willing to act against the wishes of the entire profession. At the same time, the physicians of Cologne, where the controversy was especially sharp, agreed to refuse medical service to association members except in cases of emergency. This has led to criticism of the profession by one of the ministers of the government who declared that such a step was an abuse of the right of coalition and a return to unsocial conduct. He was answered by a committee of an association formed by the physicians for the protection of their financial interests, the answer being in form of a sharp rebuke for interfering in the matter before it had been passed upon by the German Reichstag. The association, too, laid special stress upon the fact that economic necessity and need were the determining factors in urging the profession to adopt the apparently unsocial attitude it took; these factors were sufficient to overcome the traditional attitude of physicians in the pursuit of their profession.

The matter stands at present in this very unsatisfactory condition and both sides are preparing for a governmental revision of the laws relating to benevolent societies.

Tubercle Bacilli in Glandular Tuberculosis.

As is well known, tuberculous infection of the lymph nodes differs from that of any organ by the great rarity with which bacilli can be demonstrated in the lesions. On the other hand, inoculation experiments have been much oftener successful than the staining of tissue sections so far as the discovery of the exciting organism is concerned, and it is not surprising that a number of pathologists have expressed the suspicion that some latent form of bacillus is responsible for the tuberculosis of the lymph nodes, a form that cannot be demonstrated by the usual staining methods. The discovery, made by Much, that there exists a granular form of tubercle bacilli, which can be demonstrated by the use of the Gram stain alone has shown how well founded was such suspicion. That Much's granules are really the excitants of glandular tuberculosis, that is, that they are a form of the tubercle bacillus, has been apparently proved by many workers who have corroborated his findings. The use of the new staining method must change all the data usually given in reference to the rarity of tubercle bacilli in lymph nodes. Thus Koch succeeded in finding the bacilli only twice in twenty-one cases examined, while Oehlcker found bovine bacilli in four out of fourteen similar cases. In the *Münchener medizinische Wochenschrift* for March 2, 1909, Dr. Leonard Weiss communicates the results of using Much's method in looking for the bacilli. He has succeeded in demonstrating the granules that Much discovered in every one of nine cases of glandular tuberculosis, although bacilli stainable by the old methods were absent. An interesting observation recorded in the report is the finding of many granules arranged in short bacillus-like chains, a picture that lends strength to the theory that such granules are simply an involution form of tubercle bacilli that have lost their usual staining affinities.

Death of the Antivivisection Bills.

The antivivisectionists have again failed to induce the Legislature of this State to hamper scientific investigation and clog the progress of medicine by putting fatal restrictions upon vivisection, so called. A hearing on the two bills was held at Albany on March 23 before the Judiciary Committee of the

Assembly. Against the bills there appeared, among others, Drs. Egbert LeFevre, Edward R. Baldwin, James Ewing, Simon Flexner, John G. Curtis, Charles G. Stockton, and Rosalie S. Morton, and Bishop Nelson of Albany, Professor George W. Kirchwey, Dean of the School of Law of Columbia University, and President Schurman, of Cornell University. On March 24, a hearing on the two bills was held before the Judiciary Committee of the Senate at which there appeared Drs. Flexner, Curtis, Ewing, Morton, and Frederic S. Lee. On March 24 the Assembly Committee voted not to report either bill. This action kills both bills for this session of the Legislature. The Senate Committee seems to have taken no action. At both hearings the preponderance of argument was decisively on the side of science. If the final status of the matter at the present time be compared with its status a year ago, it will be seen that the situation is now much more satisfactory than then, for last year, after the hearing, the Assembly Committee took no action, while the Senate Committee voted to report one bill.

News of the Week.

Long Island State Hospital.—The State Commission in Lunacy and the managers of the Long Island State Hospital have purchased 548 acres of ground at Greenvale, Long Island, for the site of the new Long Island State Hospital which is intended for insane patients committed from Brooklyn. The site has water and rail facilities, and about 75 per cent. of tillable land. The cost is $412,000. Considerable opposition to the proposal has been voiced among the residents of the section.

Smallpox in Paterson.—A slight epidemic of smallpox is reported from Paterson, N. J., ten cases having been discovered in the first few days of April.

Pneumonia Prevalent.—Three hundred and twenty-nine deaths from pneumonia was the record in New York for the week ending March 27, as compared to 275 for the corresponding week of last year. The number of cases of the disease has been very large throughout the month.

Exhibition of the Work of the Blind.—The anniversary exercises of the New York Institution for the Blind were held on April 1, and included an exhibition of the work of the classes in manual training. Specimens of Indian baskets, reed baskets, raffia and cord work, cane seating, hand and machine sewing, knitting and crocheting were exhibited.

Quintuplets.—A North Carolina woman, the wife of a farmer, recently gave birth, according to newspaper reports, to five healthy children, three boys and two girls. The weights of the children varied from four to six pounds.

Sterilization of Criminals.—The Southern District Medical Society, of Chicago, recommends to the General Assembly of Illinois the enactment of a law requiring the sterilization of habitual male criminals, imbeciles, incurably insane and epileptic persons in the State institutions of Illinois.

The College of Physicians and Surgeons, New York.—The trustees of Columbia University announce the resignation from the Faculty of Medicine of Dr. Walter B. James, Bard Professor of the Practice of Medicine, to take effect at the close of the present academic year. To fill the vacancy thus created, the trustees, on the recommendation of the Faculty, have appointed Dr. Theodore C. Janeway to the Bard professorship, and have also appointed Dr. Evan M. Evans to a clinical professorship with a seat on the Faculty. Dr. James will retain a clinical professorship also. Dr. Janeway is a graduate of the College of Physicians and Surgeons and has been an associate in medicine at the college for the past year, having previously been on the teaching staff of the University and Bellevue Hospital Medical College. Dr. Evans is also a graduate of the college and has been for some years connected with the staff. Both men are ex-internes of St. Luke's Hospital. This is the third resignation from the Faculty of the College of Physicians and Surgeons during the present year, the retirement of Prof. Prudden and of Prof. Curtis having been announced a few months ago. Dr. W. G. MacCallum of Johns Hopkins Medical School has been appointed Professor of Pathology, but the appointment of a successor to Prof. Curtis has not as yet been made.

Gifts to Charities.—Heaton Hospital of Montpelier, Vt., will receive about $5,000 from the estate of the late Mrs. Susan B. Shumway, of that city, who died while under the care of the hospital some time ago.

Among the beneficiaries of the will of the late William P. Henszey of Philadelphia, a member of the firm of the Baldwin Locomotive Works, are the following: Hospital of the Good Shepherd, Children's Homeopathic Hospital, Homeopathic Hospital of Philadelphia, Episcopal Hospital, University Hospital, Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases, Presbyterian Hospital, Woman's Hospital, Home for Aged Couples, Friends' Home for Children, Medico-Chirurgical Hospital, Wills Eye Hospital, and White Haven Sanitarium for Consumptives, each $10,000.

Fort Dodge Hospital.—The new St. Joseph's Hospital which has been erected in Fort Dodge, Iowa, by popular subscription at a cost of about $100,000, was dedicated on March 23 and turned over to the Sisters of Mercy, who will manage it.

Schenectady Tuberculosis Dispensary.—From the time of its establishment in June, 1908, to the last of October of the same year, the Schenectady Tuberculosis Dispensary made examinations of seventy-nine patients, thirty-seven being found to be tuberculous. The dispensary has had the services of three attending physicians and a nurse, and instruction has been given in the homes of the patients as well as in the offices.

Lincoln Hospital Endowment.—More than $96,000 has already been subscribed to perpetuate the work of the Lincoln Hospital, New York, as a memorial to Abraham Lincoln, and it is hoped that the entire sum necessary, $500,000, may be pledged before the end of the year. During the last year 10,737 patients were treated at the hospital, and 150,474 days of treatment were given, of which only three and a half per cent. were paid for.

New Auto-Ambulance.—Bellevue Hospital has recently put into commission a new 20-horsepower automobile ambulance, which might well be described as a hospital on wheels. The ambulance is equipped with emergency appliances of every kind, and the inclosed part is lighted by electricity and heated by steam. It is said to be able to make more than sixty miles an hour.

A Bill to Create a Board of Osteopathic Examiners in Illinois is now in the hands of the Judiciary Committee, and a sub-committee seeks its enactment. The regular profession is working to defeat the passage of this bill on the ground that such a board is unnecessary, because the present State Board of Health issues licenses to osteopathic practitioners.

Dr. Achilles Rose of this city is about to retire from practice and will go to Athens, Greece, to reside. He intends to devote himself to the propaganda for the purification of medical nomenclature and will take part in the preparation of the lexicon which a committee of the Athens Medical Society has in hand. Dr. Rose's friends will wish him every success in his labors and many years of useful activity in this undertaking.

Dr. Lewis S. Pilcher of Brooklyn, N. Y., lectured before the surgical section of the Hartford Medical Society on March 22, taking for his subject "The Cure of Cancer."

Dr. Herman J. Boldt of New York delivered an address before the Medical Society of the Mississippi Valley on March 18.

Dr. Charles A. Drew, medical director of the Bridgewater, Mass., State Farm, has been elected superintendent of the Worcester City Hospital, to succeed Dr. Thomas Howell. Dr. Drew is a graduate of the medical department of the University of Vermont, and has had a large experience in the direction of hospitals and other institutions.

Memorial of the Late Dr. Senn.—It is believed that in a few months a memorial to the late Dr. Nicholas Senn may be erected in one of the Chicago parks, or a lectureship established. Both subjects were discussed at a recent meeting of the Senn Club, at which Dr. Alexander Hugh Ferguson was elected president. The Nicholas Senn High School is the name given by the Board of Education to a new high school soon to be erected on the north side of Chicago.

International Congress on the Medical Aspects of Industrial Injuries.—The second meeting of this congress will be held in Rome, May 23 to 27, 1909, under the patronage of the Italian Government. The programme of the congress will be arranged under seven main headings: 1, The organization of a medico-surgical service for the treatment and study of the consequences of accidents of occupation; 2, the medico-legal aspect of such accidents and the principal methods of making examinations; 3, the diagnosis and prognosis of the neuroses caused by accidents of occupation; 4, the appraisement of the working capacity before and after such an accident; 5, the influence of the mode of indemnity upon the development of post-traumatic nervous affections; 6, statistical observations, from a medical viewpoint, upon accidents of occupation; 7, functional adaptation of members disabled in an accident. Prof. Salvatore Ottolenghi, director of the institute of legal medicine, Royal University of Rome, is the president of the Congress, and the secretary-general, from whom further information may be obtained, is Dr. Tito Ferretti, surgeon in chief, Policlinico Umberto, 1e, Rome.

The American Proctologic Society.—The eleventh annual meeting of this society will be held at Atlantic City, N. J., June 7 and 8, 1909. The president, Dr. George B. Evans of Dayton, Ohio, will address the meeting on "Progress in Proctology," and Dr. Samuel T. Earle of Baltimore will give a Review of Proctologic Literature for 1908. A number of other papers and clinical reports will be read. The medical profession is cordially invited to attend all meetings.

Excursion to Atlantic City.—Arrangements have been made for a special excursion from the West to Atlantic City for the benefit of those who wish to attend the meetings of the American Medical Association which will be held at Atlantic City from June 8 to 11, 1909. The excursion will be run under the auspices of the Medical Society of the Missouri Valley and the Medical Association of the Southwest, and the special train will leave St. Louis on Saturday, June 5, at noon, arriving in Atlantic City on Monday morning. Full information may be obtained from Dr. Charles Wood Fassett, St. Joseph, Mo.

The Pathological Society of Pittsburg was organized recently with sixteen members and the following officers: *President*, Dr. Joseph S. Barrach; *vice-president*, Dr. Ernest W. Willetts; *secretary*, Dr. S. George.

The Emanuel County (Ga.) Medical Society at its annual meeting recently elected the following officers: Dr. E. T. Coleman of Graymont, *president;* Dr. L. P. Youmans of this city, *vice-president;* Dr. J. H. Chandler of Swainsboro, *secretary and treasurer.*

The Coos County (N. H.) Medical Association held a meeeting on March 17, and reorganized with the following officers: *President*, Dr. W. H. Leith of Lancaster; *vice-president*, Dr. J. J. Cobb of Berlin; *secretary and treasurer*, Dr. F. W. Evans of Coos; *board of councilors*, Drs. E. Brown of Groveton, W. H. Leith of Lancaster, and L. B. Marcou of Berlin.

Medical Alumni Meeting.—The alumni of the medical department of the University of Iowa will hold a meeting on April 27 and 28, at Iowa City. The program will consist of clinics to be held by noted practitioners, members of the faculty and others connected with the school.

The New Haven County (Conn.) Medical Association will hold its annual meeting in Meriden on April 22. The chief subject for discussion will be "Remedial Measures Other Than Drugs."

The American Society of Tropical Medicine will hold its sixth annual meeting at the United States Naval Medical School, Washington, on April 10, 1909. The program will include a review of the year's progress in tropical medicine, by the president, Dr. James M. Anders of Philadelphia, and a symposium on the prevalence and etiology of pellagra.

The East Side Physicians' Association of the City of New York.—The regular meeting of this society will be held on Thursday evening, April 22, under the presidency of Dr. C. A. Von Ramdohr. Dr. M. Girshansky will read a paper on "The Myth of Puerperal Septicemia," and Dr. Chas. Jewett one on "Puerperal Sepsis."

The Rockland County (N. Y.) Medical Society held a joint meeting with the Rockland County Pharmaceutical Association at the Lederle Vaccine Farm, Manuet, N. Y., on Wednesday of this week. A number of topics of interest to the two professions were discussed.

Obituary Notes.—Dr. D. McLean Forman of Freehold, N. J., died at his home on March 29, aged 64 years. Dr. Forman was graduated from the College of Physicians and Surgeons, New York, in 1866, and had practised in Freehold for thirty five years. He was a member of the American Medical Association, the State and County Medical Societies, and the Practitioners' Society of Eastern Monmouth, and an attending surgeon to the Monmouth Memorial Hospital at Long Branch.

Dr. Ludwig M. Michaelis of New York died at his home on March 30, aged 45 years. Dr. Michaelis was a graduate of the College of Physicians and Surgeons, New York, having received his degree in 1888, and was a member of the Academy of Medicine, the American Medical Association, the New York State and County Societies, the Metropolitan Medical Society and the Harlem Medical Association. He was also an alumnus of the Sloane Maternity Hospital.

Dr. Harry Butler, a well known resident of Bangor, Me., died after a lingering illness, on March 23, aged 40 years. Dr. Butler was graduated from the University of Maine in 1888, and from the medical department of the University of Pennsylvania in 1895, after which he served as interne at St. Joseph's Hospital, Philadelphia. He had made a special study of diseases of the nose and throat, and at the time of his death was on the staff of the Eastern Maine General Hospital.

Dr. Charles L. Kingsbury died at San Diego, Cal., where he had gone for his health, on March 14, aged 59 years. Dr. Kingsbury, who was a native of New Hampshire, was graduated from the New York Homeopathic Medical School in 1874, and had practised in Spencer and in Boston, Mass., until his health failed two years ago.

Dr. Charles W. Harwood of Worcester, Mass., died at his home on March 27, after a long illness, aged 52 years. He was a graduate of the Jefferson Medical College of Philadelphia.

Dr. John M. Kitchen of Stayton, Oregon, died on March 16, aged 67 years. Dr. Kitchen was graduated from the medical department of Willamette University, Oregon, in 1877.

Dr. Frank P. Clark of Danbury, Conn., died on March 24, of pneumonia, after a short illness. Dr. Clark was born in Danbury in 1852, and was graduated from the College of Physicians and Surgeons, New York, in 1876. He was a member of the Connecticut State Medical Society and the Fairfield County Medical Society, and a member and former president of the Danbury Medical Society.

Dr. Asa P. Tenney of Kansas City, Kan., died at his home of pneumonia, on March 20, aged 75 years. Dr. Tenney was graduated from the Harvard Medical School in 1859, and in 1877 was appointed superintendent of the Kansas State Asylum for the Insane; later he became superintendent of the Topeka Insane Asylum. In 1885 he removed to Kansas City, and from that time until his death was a member of the surgical staff of the Missouri Pacific Railway Company.

Dr. Joseph P. Fessenden, a well known surgeon of Salem, Mass., died at his home of pneumonia, on March 26, aged 77 years. Dr. Fessenden was graduated from Bowdoin College, Maine, in 1851, and received his medical education at the Brunswick Medical School and the New York Medical College, taking his degree in 1854. He was on the staff of the Salem Hospital from the time of its opening in 1874 until his death, and had served on the Salem School Board for many years. He was a member of the Massachusetts Medical Society, the Essex South District Medical Society, and the Salem Hospital Club.

Dr. A. R. Hahn of Boston, Mass., died at his home on March 30, aged 67 years. Dr. Hahn was a graduate of Dartmouth University and of the Harvard Medical School, and practiced in Chicago until the time of the great fire there in 1871, after which he returned to Boston. He was for many years on the staff of the City Hospital, and was a member of the Massachusetts Medical Society.

Dr. Milton Leroy Somers, for the last two years Health Officer of Atlantic City, N. J., died at his home on April 2 of tuberculosis, aged 38 years. He was a graduate of the Medico-Chirurgical College of Philadelphia, receiving his degree in 1897, and a member of the American Medical Association and of the New Jersey Academy of Medicine.

Dr. John Hudson Thompson of Goshen, N. Y., died at his home on April 2, aged 82 years. Dr. Thompson was graduated from the College of Physicians and Surgeons in 1852. He was engaged in active practice when the 124th Regiment of N. Y. Volunteers was organized in 1862. Hon. Edwin D. Morgan, the State Governor (1859-63) commissioned him as regimental surgeon and he was soon made surgeon-in-chief of the brigade and division with the rank of major. Dr. Thompson was popular as both soldier and physician in caring for the ill and wounded.

Dr. George O. Barclay of Philadelphia died at the University of Pennsylvania Hospital in that city on April 3, of peritonitis, aged 33 years. He was a graduate of the Medico-Chirurgical College of Philadelphia, and was a famous football player at Lafeyette University.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

MORPHOLOGY AND VARIATION OF THE SKULL—FRACTURE OF THE BASE—HUNGER PAIN—CHINA AND MEDICAL SCHOOLS—DEATH RATES INCREASING—OBITUARY.

London, March 19, 1909.

"The Morphology and Variation of the Skull" was the subject of a course of Hunterian lectures at the Royal College of Surgeons, delivered last month by Dr. William Wright, lecturer on anatomy at the London Hospital Medical College. Variation, he observed, opens the whole subject of evolution, a theory as old as Anaximander and Archelaus, and he briefly stated the three theories: Lamarck's, the earliest, which recognizes in nature a power of effecting adaptive variations, but errs in assuming that an animal controls this power itself; Darwin's, which is differently understood by Huxley and Wallace, the former accepting natural selection acting on accidental variations as an adequate explanation of the forms of life, as if the whole world, a world in which law, order, and intelligence prevail, were the outcome of accident. But Wallace regards variation as due to the mysterious powers of life, to which the lecturer saw no alternative and suggested whether the origin of species should not be ascribed to these powers, natural selection being insignificant. A third theory, supported by Bateson, considers variation is not always slow and continuous, but sometimes discontinuous and giving rise to mutations. It was to be noted, however, that natural selection could not directly produce anything—could only encourage or suppress—and artificial selection, though it might be more rigorous, could not effect specific variations even in the lowest microorganisms.

The lecturer then described the morphological

divisions and variations of the skull and traced its evolution. To emphasize the importance of remembering retrogression as well as progression, he referred to the life history of the ascidia, the larval state of which is vertebrate, possessing a notochord and sense organs, but as it develops sinks to the bottom of the ocean, where its higher faculties decline and it spends its allotted span in a state of "vegetative monotones." The amphioxas, too, suffers a degenerative change, though it retains its vertebrate character. In these two organisms the beginning of a cranium is seen as a membranous sac enclosing the anterior end of the central nervous system. Passing to the cyclostata, Dr. Wright found differences, not fundamental, in the skulls of those living now, but much greater in certain extinct fishes from the old red sandstone—as if nature had made an abortive attempt to produce craniata or was herself undergoing an evolutionary process. If this is strange doctrine to those who hold only by a material evolution, he replied that "no one has proved, no one ever now is likely to prove, that matter itself is other than subjective." Such a recognition of Berkeleyan philosophy is quite refreshing among these anatomical details. Passing to true fishes, the lecturer remarked that the few elasmobranchs and ganoids living to-day are only scanty survivors of a rich and varied fauna which alone upheld the vertebrates through the Silurian and Devonian periods.

Before leaving fishes mention was made of some parallels they exhibit with land animals, *e.g.* some are viviparous, some oviparous, the mustelus possessed a placenta, cord, and amnion; in pteroplatæa there is an approach toward suckling the young. As a final reference, Dr. Wright mentioned the habit of the butter fish of coiling its body around its eggs, as there possibly was the beginning of that "maternal instinct which leads the hen to gather her brood under her wings, the prettiest scene in nature and the most attractive simile in literature."

Coming to amphibia, the lecturer found evolution progressed along two distinct lines, the rhynchocephalic and anomodontine, the former leading through many extinct forms to living reptiles and to the still more highly specialized birds, which lie distinctly apart from the main line of vertebrate descent. Through the latter he came to the monotremes, the lowest of mammals. Of course, in the various links the skull was the point most considered, and perhaps no other region of the body could so well furnish evidence of variation adapted to purpose, for in it were seen most admirable devices distributed throughout the zoological kingdom—devices which create wonder and disarm criticism. If further proof were asked that living forms owe their birth to an unknown power operating in nature it could be found in the phenomena of parallelism, which clearly show that nature progresses, not eratically, but along old, well-tried paths. So the way in which many amphibia can regenerate limbs indicates in them an intelligent force of which they can be only dimly conscious. If this mysterious force be admitted, there is no necessity for natural selection to be regarded as dominant in evolution and artificial selection is practically impotent. Recognizing this mysterious force as the *vera causa* of evolution, Dr. Wright asked if we were wise to push inquiry further, and answered without hesitation in the affirmative, for the question becomes psychological, and that is intelligible, for he held with Descartes that we "know more of mind than we know of body, the immaterial world is a firmer reality than the material." As to how the mysterious power works nothing could be said, unless that it did not show human intelligence it acted in a way the human intellect can follow and in some degree comprehend. An impressive fact was the enormous apparent waste of extinct animal form, but it might be that each evolved in a high degree some particular attribute with which some remote variation could be effected. That nature should act in a human manner was not surprising, as human intelligence is her highest achievement and probably her last stage mentally and morally. Morally the knowledge of right can go no further, and as to whether a human intellect will ever surpass that of Aristotle the lecturer confessed he remained skeptical.

At the Medical Society of London on the 8th Mr. L. B. Rawling had a paper on the surgical treatment of fracture of the base of the skull. As any practitioner may be called upon to treat such a case, always an anxious one, a few points may be of interest. He remarked that profuse hemorrhage from the auditory meatus suggested extradural extravasation and an extensive fracture of the petrous bone probably involving the tegmen. Plugging the meatus was wrong; it hindered the escape of blood, one factor of compression. Syringing, too, was dangerous and might cause meningeal infection. From a study of about 300 cases Mr Rawling classified them in three groups: (1) Where the temperature rose steadily to 103° or more, marked reaction from the collapse stage and definite signs of compression. (2) Temperature rising to 100°-101° and remaining for a time, the later rise or fall indicating death or recovery—a sort of crisis, therefore. (3) Temperature keeping subnormal from the first, the prognosis then being death in a few hours. Bleeding would reduce intracranial pressure. As to operations, that designed by Harvey Cushing had several advantages, especially the possibility of drainage through the split muscle rather than through the scalp and the use of the muscle against a tendency to hernia. Lumbar puncture was pronounced useless, even for diagnosis. Blood in the cerebrospinal fluid merely suggested intradural hemorrhage, and Mr. Rawling had never seen it benefit these cases.

Hunger pain, so called from its coming on some four hours after food and being relieved by eating something, has long been regarded as suggestive of duodenal ulcer, especially as it is usually situated on the right side. At one time, indeed, it was thought by many to be pathognomonic, but now it is mostly considered to be a suggestive clinical symptom, which may be present in other conditions. Dr. James Little of Dublin showed a specimen at the academy lately from a man of about sixty (which he thought the most common age) who had had right-sided pain in proportion to the solidity of the food he took and two bleedings from the bowel, but who did not think himself very ill. After three or four days in hospital, severe hemorrhage and later vomiting of blood proved fatal. At the post mortem an ulcer was found and a ruptured artery in its floor, the head of the pancreas. A second ulcer was also found in the duodenum. Mr. Wheeler said he had had five cases, one verified by post mortem, the four others by operation. In the fatal case the duodenum was rotten and leaking, but a definite ulcer was not detected at operation. Mr. Stokes said Mayo found 69 per cent. of ulcers were in the duodenum and even more in males, but gastric ulcers were more frequent in females. He believed hunger pain was common in any lesion of the middle gut. Dr. Moorhead had had two cases, one a woman with typical hunger pain, the other a young man who never had it. Dr. Cahill said duodenal ulcer began earlier than usually supposed, and when seen at the age of sixty or so was perhaps the final stage of a very chronic digestive trouble. A definite time relation could be found by giving a slowly digestible meal to delay the pain. But the pain was found in other conditions.

A very distinguished company attended at the Mansion House on Tuesday, over which the Lord Mayor presided. The object of the meeting was to promote a scheme proposed by the China Emergency Committee to help existing philanthropic and religious agencies in China. Sir Robert Hart strongly espoused the cause and declared that to-day is the opportunity for the West to help the East—the day the "East is rubbing her eyes and standing on her feet." The American and the Chinese Ambassadors were both present. The point to interest you is that it is proposed to establish four medical training colleges in connection with existing hospitals in four centers. These are mostly supported by missionary societies, and the committee is to work through them. Other branches of knowledge are to be taught and translations of Western books undertaken, so the colleges, if established, will be incipient universities. On every hand we are assured China is awakening and desirous of Western science and learning. As regards medical training, it is to be hoped that this will be kept strictly in the hands of qualified medical men. There are many associated with the missions and their hospitals. It would be a sad blunder to allow the missionaries themselves to pose as doctors. A few would perhaps like to, but certainly not the most useful.

Our death-rates have been rising during the last month due to a large extent to measles and influenza, both of which have been prevalent. The deaths registered from measles in the last four weeks have been successively 93, 94, 92, 105. From influenza, 25, 36, 66, 101. For the same weeks the annual rate has averaged 21.4, being 3.8 above the mean for 1904 to 1908.

Dr. William H. Day of Norwich, where he passed a long and useful life, died on Monday, the 13th inst., at the age of eighty-five. He qualified as long ago as 1845. He soon after began practice in his native city. For many years he had the confidence of both rich and poor—the latter having always appreciated his kind attentions. He filled many medical offices in his time and always with satisfaction, earning continuously esteem and gratitude.

Another prominent senior practitioner in the provinces died on the same day, viz., Dr. J. H. Keeling, aged seventy-seven, consulting surgeon to the Royal Hospital and the Women's Hospital, Sheffield. He was M.D. Edin. 1852. He joined the Turkish contingent in the Russian war and received the Medjidich Order. He settled in Sheffield afterward and became a lecturer in its medical school and an active member of the Medical Society. His health had failed of late years and he retired in 1906.

Lieutenant-Colonel J. E. Fishbourne, R.A.M.C., M.D., F.R.C.S., died on the 16th, aged sixty-seven. He joined the army in 1865 and retired in 1885. He served in the Afghan war, 1878-1879, receiving the medal, and in the Mahsood Waziri expedition in 1881. He took part in the Soudan campaign, 1884-1885, and received the medal with clasp and bronze star.

Surgeon-Major Frederick Sairgnac Stedman, formerly of the Bombay Army, died on the 16th, after a few hours' illness, at the age of eighty.

OUR LETTER FROM COPENHAGEN.

(From Our Regular Correspondent.)

SOME PHYSICAL AND CHEMICAL ACTIONS OF LIGHT-RAYS.

COPENHAGEN, March 13, 1909.

At a meeting of the Medical Society of Copenhagen Dr. Aage A. Meisling read a paper on his discoveries regarding the properties of the light rays. He said that the utilization of the curative and antibacterial properties of the light rays would rest on a far firmer foundation if we had a better knowledge of the decompositions which the rays provoke in the substances forming the different tissues of the organism, particularly the proteins and other colloids. D. Meisling has experimented chiefly with plaques of gelatin and has found that pure gelatin is in itself sensitive to light to such a degree that an exposure of five to ten minutes' duration to a Bang lamp suffices for the production of demonstrable alterations, later to be described. The sensitivity to light is increased very considerably by coloration of the gelatin with certain anilin dyes, *e.g.* erythrosin, eosin, or auramin. These dyes have a catalytic action. After exposure to light rays pure gelatin gives the reaction for formaldehyde. The blue, violet, and ultraviolet rays possess the strongest action in this respect. The methods for demonstrating and measuring the light action on gelatin are either physical or chemical. As an instance of the first class of methods, Dr. Meisling has shown that the illuminated parts of a pure gelatin plaque have a diminished faculty for water absorption, so that relievos arise when, after exposure to the light, the plaque is placed in water, the sunk spots being identical with those having been illuminated. Very beautiful relievos may in this way be obtained by employing a gelatin plaque sensibilized by erythrosin and an ordinary photographic negative. Exposure to light alters the solubility of gelatin, a fact which may easily be demonstrated by placing a gelatin plaque in water, when only the non-illuminated parts will dissolve. As will be seen, the physical changes brought about by illumination represent a hardening and precipitation of the substance.

One of the chemical changes that take place in illuminated gelatin is an oxidation, another the mentioned formation of formaldehyde. This last chemical process explains satisfactorily the precipitation and hardening. A further peculiar faculty of illuminated gelatin is this, that the parts of a gelatin plaque that have been exposed to the light, when placed in a solution of anilin dye, attract the coloring matter and become themselves strongly colored. If, for example, a gelatin plaque, after exposure to the light under a photographic negative, is placed in a fuchsin solution, after a few hours a beautiful red-colored copy of the negative is seen on the gelatin plaque. Under certain conditions the light produces, besides formaldehyde, also hydrogen peroxide in the illuminated gelatin. This formation of hydrogen peroxide is due to the presence in the illuminated substance of sulphuric acid and resinous matter, not to the gelatin itself. Both formaldehyde and hydrogen peroxide are oxidizing agents, though acting in a different way. When acting together they bring about very strong oxidations of an extremely complex nature. With mixtures of hydrogen peroxide and formaldehyde Dr. Meisling has succeeded in obtaining the same reactions *in vitro* as those that are used for the demonstration of oxydases. He therefore considers the oxydases to be simply mixtures of formaldehyde and hydrogen peroxide.

Summing up, he said that as a result of his researches the enigmatical vital processes particularly connected with the colloids might to a certain extent reasonably be considered as depending on simple physical and chemical laws.

Professor Carl J. Salomonsen and other speakers congratulated Dr. Meisling on his important researches that appeared to shed light on hitherto rather dark ground.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

CHOLERA—IMPROVED CONDITIONS IN MANILA—CAMPAIGN AGAINST ADULTERATED BEVERAGES—NEW WATER SUPPLY—BILIBID PRISON HOSPITAL—NEW HEALTH INSPECTORS OF THE BUREAU OF HEALTH.

MANILA, P. I., February 9, 1909.

The cholera, which has prevailed in Manila during the month of September, and which was the cause of the great Atlantic fleet not landing here upon its first visit, has produced considerable activity in local circles. Among other things, the Manila Merchants' Association appointed a committee to investigate the cause and fix the responsibility for the presence of the disease in Manila. This report was made public December 29, and the blame for existing conditions was practically laid upon the Municipal Board, which is responsible for the administration of the city of Manila, because it failed to carry into effect recommendations which had been persistently made during the past five years by the Bureau of Health. This opinion was arrived at after the committee visited a large number of insanitary places, which showed that the building and other ordinances, the enforcement of which was the duty of the Municipal Board, had been continually violated. The evidence showed that the health authorities had repeatedly protested against such a condition of affairs, but without avail.

On account of the extreme desirability of eradicating cholera from the city as soon as possible, many rigorous measures were taken at this time in order to produce the desired result in the shortest period. Among other things the insanitary nipa houses, which had been such a great cause of concern to the Bureau of Health for many years, are being rapidly moved to more sanitary sites, and the swamps upon which they stood are being either filled in or drained. The Municipal Board, in spite of many vigorous protests from the Director of Health in the past, had not intended to enforce their removal until 1914.

The lack of public midden sheds has also, no doubt, been an important factor in the spread of the disease in times when flies were plenty, and on account of the pressure brought to bear by public opinion on the municipal officials they have already constructed forty-five additional sheds of this character.

Public hydrants have been installed and many insanitary wells, which it has been impossible to close heretofore, have now been permanently filled in.

The San Lazaro estate, which the city of Manila has heretofore claimed could not be improved without an expenditure of at least $50,000, has been greatly improved by draining the same at an outlay of about $2,000.

The improvements which have been brought about in Manila in the past six months are concrete evidence of what aroused public opinion may accomplish. The appeals of the health authorities in the past have fallen upon deaf ears, and they were being held responsible for a situation that they were unable to remedy under existing legislation.

The active campaign which was commenced here against the importation of fermented beverages which did not comply with the provisions of the Food and Drugs Act has been temporarily suspended. On account of recent developments which have taken place in the United

States, it has not been deemed advisable to enforce the provisions of this Act until the Department of Agriculture issues final rules which shall govern the manufacture, sale, and labeling of these products.

The new water supply for the city of Manila, which comes from an uninhabited water shed, was made available for use November 13, 1908. It is notable that the per capita consumption of water has already increased considerably, an average of thirty gallons per capita being used, as against twenty gallons per capita formerly.

The new $100,000 hospital for Bilibid prison, which has been under construction for the past few years, is now practically complete, and the tuberculosis wards are already being used. This is one of the first modern hospitals to be completed since American occupation of the islands.

The sixth annual meeting of the Philippine Islands Medical Association will be held in the lecture rooms of the Philippine Medical School from February 11 to 13, inclusive. A number of visitors from abroad will be present.

The Bureau of Health is about to increase its number of medical inspectors and the Civil Service Commission at Washington has been asked to recommend five men for appointment. The entrance salary is $1,800 per annum and men with records are eligible for promotion in several years' time to positions of $3,500 per annum. The work not only is of the kind that ordinarily falls to the lot of a health inspector, but there are also many opportunities for medical and surgical experience.

ZOOPHIL PSYCHOSIS.

To the Editor of the Medical Record:

Sir:—Will you permit me to suggest the term "zoophilitis" in place of zoophil psychosis, under which title Dr. Charles L. Dana has published a highly interesting paper describing abnormal regard for animals, in your esteemed journal of March 6. A. Rose, M.D.

New York.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 25, 1909.

Surgery of the Bile Passages, with Special Reference to the End-Results.—J. C. Munro discusses the question and gives summarized histories of six personal cases. His conclusions follow: (1) An analysis of our cases demonstrates that jaundice is present in a majority of all, even the simple gall-bladder cases, at some time, and that a very large majority of common duct cases have jaundice. (2) That the pancreas is not infrequently pathological, as determined by examination of the open abdomen. (3) That adhesions are present in a large majority of cases and may be the direct cause of symptoms rendering all medical treatment more than futile. (4) That pulmonary complications must be reckoned with in prognosis, but that they are less frequent than anticipated. (5) That cholecystotomy is normally a more suitable operation than cholecystectomy unless the gall-bladder is definitely functionless. (6) That recurrence of symptoms may be due to adhesions or a contracted gall-bladder as well as to overlooked stones. (7) That toxemic cases are best treated medically until the acute state is passed. (8) That fatal capillary hemorrhage may be controlled to an extent not yet determined, by the use of fresh animal serum.

A Case of Pseudo-Hermaphroditism.—W. L. Harris refers to the case of a person of seventeen years, brought up as a girl, to whom he was called as she was having a "fit." Entering the room, he found the unconscious person had thrown off the bed clothing, disclosing a penis six inches long and three in circumference. The child had been born with a small perforate protrusion in the genital region, which the physician in attendance had told the mother was an enlarged clitoris. It had grown up with some of the characteristics of the male sex, but with a preference for those of the opposite sex. Examination under ether revealed absence of scrotum and no evidence of testicles or spermatic cords. At the base of the penis was an opening about one and a half inches long, with the pinkish mucous lining thrown into longitudinal folds. An instrument passed two inches into this opening entered the bladder. No uterus could be discovered. It was believed that this was a definite case of androgyna and the patient's parents were advised to change the clothing from that of a girl to that of a boy. At seventeen she had her first epileptiform convulsion and the present was probably the third or fourth. The removal of the penis was advised and done without incident and the epilepsy ceased. The later development of this person was that of a sexual pervert. Some time after, a young man who had known her as a girl proposed marriage and could not be dissuaded therefrom, although the exact state of affairs was explained to him. To satisfy the parents an exploratory laparotomy was done, but no uterus, broad ligament, or ovaries were found. The two young people eloped and the result of attempted sexual relations was a return of the epileptic attacks. Sexual desire became a mania in this developed pervert. Epilepsy became so frequent that it became necessary for the young man to leave his "wife." Separate living greatly improved "her," but resumption of living together brought about again a return of the epilepsy, and the "wife" was committed to the asylum. While there she contracted syphilis. The later history of the case is not given.

New York Medical Journal, March 27, 1909.

Eucalyptus in Leprosy.—H. C. Hollman, a resident of the Hawaiian Territory, thus describes the manner of using the remedy. For medicated baths the following formula is given: Take of thoroughly cut eucalyptus leaves, ¼ lb.; of Ohia leaves (mountain apple—jambos malaccensis), ¼ lb.; ground hæmatoxylon bark, ground hemlock bark, 1 oz. This is tied in a small muslin bag. To make bath, place bag in 5 gallons of water, boil for one hour, of this take 2½ gallons and add to the daily bath. For internal use the following is the formula: Take eucalyptus leaves, cut up thoroughly and place in still, cover with water, and place on fire. From a 5-gallon still we get 3 gallons of distilled eucalyptus. Directions for using this distillate: Take ½ teaspoonful in a glass of sweetened water three times a day. The dose is gradually increased until the patient is taking a tablespoonful three times daily. The author has obtained, after two years' treatment, the following results: (1) The glands of the skin are stimulated. The skin now presents a much clearer, cleaner, brighter, healthier appearance. (2) It softens the thickened, indurated skin and underlying integument. The skin becomes softer and more pliable, "Leonine" facies becomes less marked. Two cases, one reported as showing marked improvement, are now *not* the exception, but many more lepers show this decided improvement. (3) Marked improvement in leprous neuritic pains. This pain is most intractable to remedial agents, but under baths and internal eucalyptus many are relieved to a great extent. The numbness of the hands and feet (a feeling as if the parts were asleep) becomes less marked in many cases. It also relieves the coldness of these parts. (4) Itch, leprous, as well as parasitic, is cured. Formerly there was an almost constant prevalence of one or the other variety of itch. To those who use this treatment, itch has become a rare disease or symptom. (5) Many cases of leprous excoriations, ulcerations, erosions, and abrasions of the skin and mucous membranes are healed. The sores of whatever variety except where the bone is affected are stimulated, old scabs and crusts are thrown off, and healthy granulations appear, and finally healthy, rosy skin covers it over. (6) Swollen head fever, first described by Dr. Goodhue, has ceased to assume epidemic proportions, and has, in fact, largely disappeared. There have been *no* attacks in those using baths, etc. (7) Leprous fever, produced by exacerbation of the disease, or perhaps by fresh invasion of the germ has shown a decided decrease in the number of patients. Many have not had an attack since starting treatment two years ago. The author's experience is based on 275 patients who have taken the baths more or less continuously, and have taken eucalyptus internally in some form, either distillate or the oil, with strychnine. Those patients who show the most marked improvement have followed the bath by an inunction of a salve composed of: R. Oil of eucalyptus, oil of chaulmoogra, equal parts. M. Among those who have regularly taken the baths and internally eucalyptus and strychnine, the death rate has been less than 5 per cent., and less than 2 per cent. due to leprosy.

Painful Heels.—I. D. Steinhardt finds a most frequent cause of this condition to be an acute productive inflammation of the oscalcis, and the underlying trouble may be due to a gonorrheal, rheumatic, traumatic, and gouty rheumatic. The full pathological findings are given of one case of the gonorrheal variety. The patient usually complains at first of general pain in the toes and foot,

which after a little time becomes localized in the heel itself. Examination of the heel proper shows general tenderness, with a point of exquisite pain on pressure of the sole of the foot immediately in contact with the tubercule of the os calcis. This pain is such that ofttimes the fear of it is sufficient to prevent the patient from putting his feet to the ground, and he uses crutches and various other means to get about without having to put his weight upon his feet. An *x*-ray picture will show bony spicules protruding from the os calcis with a periostitis of the surrounding bone or a very much enlarged tubercle of the os calcis. Treatment consists in the removal of the offending exotosis and later of the underlying cause. Operative details are as follows: (1) Apply Esmarch bandage. (2) Usual cleansing of entire foot for operative procedure. (3) Apply tincture of iodine to line of incision. (4) Make an incision about 2 or 2½ inches long, terminating at a point about ½ inch behind the tubercle of the os calcis. This incision should be right down to the bone, and in the middle line. (5) Insert retractors and locate exostosis at bottom of wound. (6) Chisel away exostosis with a grooved chisel and scrape the bone with a sharp spoon until the surface is smooth and seems healthy. (7) Wash out with sterile normal salt solution. (8) Close wound without drainage, with interrupted catgut sutures. The patient should rest in bed for about three days, and may then, if everything is going along smoothly, be allowed to sit up. At the end of two weeks, the feet may be put to the ground, and after twenty-one days the patient should be around as usual, continuing, if still necessary, the post-operative treatment.

On External Roentgen Treatment of Internal Structures (Eventration Treatment).—Carl Beck gives the histories of eight cases of abdominal cancer in which this treatment was used and three of which are now alive and well. The plan consists of opening the abdomen, bringing the malignant area to the edges of the wound, fastening it there so that the *x*-ray may be used directly upon it, and later releasing the affected area and dropping it back into the abdomen, which is then closed in the usual way. The author is not too sanguine as to ultimate results. In regard to his first two cures he says that the future alone can show if the cures are permanent. Perhaps, he adds, they were only most favorable cases for this mode of treatment, while the fatal ones were received in a very much advanced stage, and might have been more answerable to the Röntgen therapy at an earlier period. The type of the carcinoma texture must, as we know, also have a marked influence. It is my experience, as well as that of other investigators, that in some neoplasms the process of destruction is rather accelerated by the Röntgen treatment than prohibited. If we could define the exact reasons for this strange phenomenon we would learn more about the indication and the eventual prognosis of this kind of therapy. It is remarkable, however, that even in my fatal cases a short improvement took place.

The Intracranial Causes and Operative Treatment of Trigeminal Neuralgia.—J. B. Deaver enumerates some of the common causes of trigeminal neuralgia which arise within the skull. Predisposing causes are the neuropathic diathesis, exhausting maladies, loss of blood or tissue juices, anemia, cachexia, senescence, and arteriosclerosis. Cold, exposure, overexertion, and mental strain act similarly. The mineral poisons, toxins of diabetes, gout, Bright's, etc., are all included. The various infectious diseases, fracture at the base of the skull, abscess along the course of the nerve, carotid aneurysm, tumors of the Gasserian ganglion, tuberculous and syphilitic granulomata, cholesteotomata in the region of the ganglion are also causes, and that group of cases is also to be thought of in which neuralgia major, tic douloureux, epileptiform neuralgia are present and raise a doubt as to whether surgery can intervene with benefit or not. The author then traces the history of the development of surgery as applied to this affection, dwelling particularly on extirpation of the Gasserian ganglion. He says that to those who have not had the opportunity of observing cases of major neuralgia, this operation may seem somewhat heroic to employ for the relief of a condition characterized by pain without danger to life. By those, however, who have seen the abject misery it can cause, leading in not a few instances to suicide, or to the addiction to morphine, the operative treatment, with its comparatively present low mortality and not very great deformity, will be hailed as a triumphal offering of surgery to humanity.

Journal of the American Medical Association, March 27, 1909.

Human and Bovine Tuberculosis.—F. M. Pottenger reviews the points of difference and resemblance between human and bovine tuberculosis bacilli, stating the opinions of others and giving the results of his own observations. He believes that we are warranted in assuming that these bacilli are not only different, but antagonistic, though originally from one parent stem. He makes a comparison between cowpox and smallpox, and believes that the same immunity can be conferred, though with greater danger, by children taking in bovine bacilli in small numbers. His experience has taught him, if he interprets his observations correctly, that few patients do equally well on treatment with both forms of bacilli; some are improved by one and irritated by the other. Pottenger considers it fairly established that human and bovine bacilli are different and that cattle can be immunized against bovine bacilli by inoculation with moderate numbers of human bacilli. Their resistance, however, can be overcome by overwhelming or prolonged infection. Human beings are sometimes infected with bovine bacilli. Reasoning from all the facts, he concludes that the toxins of the two forms are different, but, judging from the reaction to the infection from the two types, it appears that both are able to produce tuberculosis in the human body, but that the localization of the two infections is more or less constant. It has been found that infections of the lungs, larynx, and intestines are best treated by tuberculins as a rule made from bovine bacilli. These infections are most probably of human origin. Infections of the bones, glands (as a rule), peritoneum (with effusion), ear, and genitourinary tracts as a rule are best treated by tuberculins made from human bacilli. These infections are probably produced by bacilli of bovine origin. Reasoning from the analogy, the fact that human bacilli will immunize cattle against infection with bovine bacilli would suggest that bovine bacilli might immunize human beings against human bacilli; and, if our belief that tuberculosis of the bones is of bovine origin is true, and our observation that persons suffering from bone lesions rarely suffer from tuberculosis of the lungs is correct, we have clinical evidence which supports the fact that immunity in human beings against human bacilli may be produced by infection with bacilli of the bovine type.

Tubercle Bacilli in Milk.—A. F. Hess examined samples taken from the large forty-quart cans which constitute a large proportion of the New York City milk supply and are often the same as the bottled milk. In 107 samples 17 or 16 per cent. were found, by inoculation tests on guinea pigs, to be tuberculous, tubercle bacilli being found in the guinea pig on autopsy. Tubercle bacilli were not discovered by direct microscopic examination, but only by animal inoculation; cream, as well as sediment, was found infective. Tubercle bacilli were also detected in a sample of "commercially pasteurized" milk, claimed to have been heated to 160° F. for forty seconds, showing that this name is misleading and suggesting that only such milk be called "pasteurized" as has been heated for a length of time and to a degree sufficient to insure its being a safe food. In all but one instance the bacilli found were of the bovine type. In the exceptional case a human type was found, showing that human contamination of milk is possible and must be guarded against. A number of infants and young children who drank milk containing tubercle bacilli, when examined one year later, seemed in average health. A fourth of the number, however, reacted to tuberculin. One of them was in poor physical condition and had suffered from a recent glandular affection. Probably 90 per cent. of human tuberculosis is due to infection from human beings, but we are not, therefore, justified in neglecting the danger from the bovine source, as even a very small percentage from this cause means thousands of cases. As an immediate safeguard, Hess recommends pasteurizing or boiling all milk not coming from tuberculin-tested cows. There should be a great many more inspectors of herds and finally all cows should be tested with tuberculin, and, if found reacting, should be condemned or isolated.

Facial Deformities.—E. S. Talbot points out how in the evolution of the race certain structures develop and others are lost for the benefit of the organism as a whole. With the greater development of the brain, other structures of the head, the facial bones, the jaws and teeth especially, decrease in size and recede, making the face more perpendicular. How rapid this change may be is shown by the changes in the cranial and facial characters of the African race in the northern States of this country. In the white race the changes in the jaws are shown by the disappearance of the

third molar, which Talbot found wanting on one or both sides in one or both jaws in 47 per cent. of patients over twenty-five years old. The lateral incisor comes next. It was missing in about 6 per cent. of patients. These parts undergoing such rapid changes are structures with transitory characteristics and are more readily involved in disease than others. In the development of men from the primitive cell, periods of stress due to readjustment to environment occur, some during development and others during involution. The first period of stress, and the most important one as regards facial and dental development, occurs about the eighteenth week of fetal life. The second occurs after birth, at the time of the development of the first set of teeth. Arrested development of the jaws is usually accompanied with abnormalities also in the nasal bones and mucosa, though neither is as dependent on the other as has been supposed, both being the result of an unstable nervous system; the two conditions go side by side, and the successful treatment of one must have a favorable effect on the other. The perpendicular line is the dividing line between the normal and abnormal facial angle. Deformities of the face, nose, jaws, and teeth rarely require treatment except under conditions where these structures develop inside of the perpendicular line drawn at right angles to a line from the root of the nose to the external auditory meatus.

The Opsonic Index.—E. F. McCampbell publishes a description of a method devised by himself which makes the determination of the opsonic index available to the general practitioner with limited laboratory facilities. He incubates a culture of the bacterium to be opsonized at 37° C. for from eighteen to twenty-four hours, then washes it off with a small amount of sterile 0.85 per cent. sodium chlorid and 0.8 per cent. sodium citrate solution. The bacterial emulsion is drawn up to the mark 0.5, and then on up into the bulb of the leucocyte blood-counting pipette of a hemocytometer. The blood of the patient whose opsonic index is to be determined is then drawn up to the mark 0.5, then on up into the bulb, where it is thoroughly mixed with the bacterial emulsion. The sodium citrate in the bacterial emulsion precipitates the calcium salts and prevents the coagulation of the blood which would occur without greater dilution with salt solution. When the materials have been mixed the solutions are blown into the capillary portion of the pipette and a strong rubber band placed over the ends lengthwise, thus practically sealing it. The pipette is now ready for incubation, which may be accomplished in a regular incubator at 37° C., or, if no incubator is available, the pipette may be incubated in the operator's axilla. The pipette must be frequently rotated. After incubation for fifteen minutes or any desired period the material is blown out on a slide, the smear made and stained with carbothionin blue or some other equally good blood stain. McCampbell says that experimental work suggests that the sodium citrate causes a slight reduction in the amount of phagocytosis, probably due to some slight effect on the opsonins, but he does not know whether this effect will be noted with all species of bacteria. By this method the index can be determined as quickly as an ordinary blood count can be made. Further results with it will be noted later.

The Lancet, March 20, 1909.

On the Cultivation of Spirochæta Duttoni.—C. M. Duval and J. L. Todd give the following note on the preparation of the suitable medium. The yolks of two fresh hen's eggs are carefully separated from the whites under aseptic precautions and dropped into a 200 c.c. Erlenmeyer flask, to which have been previously added 100 c.c. of a sterile mouse decoction, made by boiling the skinned bodies of six mice in 500 c.c. of water. The mixture is thoroughly shaken until it is homogenous, when 5 c.c. of defibrinated sterile mouse blood are added. The flask is now sealed to provide drying of the medium and placed at 37° C. for from six to eight weeks, until the mixture undergoes partial digestion. The semi fluid mass first becomes solidified and finally, through autolytic action, is broken down to a grumous, mush-like mass. In the author's experience this partial autodigestion of the mass seems essential to the multiplication of the spirochæta. If the egg mixture is coagulated at higher temperatures, it seems to be no longer suitable for the growth of the parasites.

An Investigation into the Leucocytes of Epidemic Cerebrospinal Meningitis.—W. Dow has made a series of observations and collected his results in tabular form. He says (1) that cases of the disease are always accompanied by a leucocytosis, whether the attack is acute, abortive, mild, or chronic. (2) That the character of the leucocytosis is practically the same in all instances, both adults and children, and is the result mainly of an increase in the number of polymorphonuclear cells. (3) That nevertheless a lymphocytosis may be very occasionally observed in infants and young children. (4) That there is a relative decrease of the large mononuclear elements alike in fatal and non-fatal cases, though less marked in the chronic type. (5) That in the first three groups there is sometimes an absolute decrease of the large mononuclear elements and occasionally total absence of these cells. In the chronic group, absolute decreases like relative decrease is little marked. (6) That eosinophile corpuscles in acute fatal cases are always present, though present in varying degree in all the other groups. As regards diagnosis, the leucocytosis is of value only as excluding typhoid fever.

X-Ray Carcinoma.—C. W. Rountree says that there are now on record in Great Britain at least eleven cases of carcinoma following exposure of workers to *x*-rays, and one case has proved fatal. Full descriptions are given of one case. The practical point relates to the well-known treatment of malignancy with this therapeutic agent. There has been and still is, says the author, considerable divergence of opinion not only as to the kinds of growth which should be subjected to treatment, but also as to the manner in which the best results may be obtained. All observers are agreed, however, that it is only in very superficial conditions that amelioration can be confidently anticipated. Of all malignant growths rodent cancer is the most superficial and it is the only variety in which really good results have been obtained. But even in this condition the results are discordant, in some cases the tumor disappearing after two or three exposures, in other cases healing, only to break down again, or not healing at all. It is possible that in certain instances the dose administered has been so large as to have induced a condition analogous to an *x*-ray burn, or in other cases it is probable that a dose just sufficient to induce retrogression of the superficial parts of a growth may, in the deeper portions, stimulate to increased activity.

British Medical Journal, March 20, 1909.

Bee Stings and Rheumatism.—E. T. Burton contributes another article on this subject, referring to cases previously reported, and adding additional new ones. Some pertinent words are added on the management of bees. The general tenor of the report is that bee stings are distinctly beneficial in rheumatic cases.

Some Insufficiently Recognized Points in the Diagnosis of Disease.—Dyce Duckworth urges the importance of a study of the patient no less than of the disease, and illustrates his points by reference to tuberculosis, rheumatism, myxedema, cretinism, etc. In regard to tuberculosis, he notes the so-called preliminary scrofulous period during which the patient presents a soil ever ready to tuberculous infection. These cases are veritable forcing grounds for all kinds of vicious microbic invasion. They have every prevalent infection and are always very sick with it. They are not tuberculous and never need become so, but every hygienic precaution is required to keep them well. One of the most striking features of the arthritic diathesis is its resistance to tuberculous infection. If it is acquired, it has a hard struggle to progress, and is easily arrested or held in check for long periods. There are such things as blends of constitutions, intermixtures of diathesis, etc., as struma and rheumatism, gout and struma, etc. Arthritic subjects are peculiarly susceptible to the gonococcal virus. There is also a neurotic habit of body in which we find instability of the nerve centers, with a tendency to break down in various parts of the cerebrospinal axis, a condition plainly inherited and transmissible, often blending with other proclivities, as chorea, which presents a distinct rheumatic infection, together with nervous erethism and instability. Myxedema and cretinism in an early stage may long remain unrecognized, unless we are on the lookout for the peculiarities of the disease as disclosed by a change of physiognomy and habits. In cases of apparently simple anemia, especially in middle-aged males, we may sometimes discover the reason of our inability to promote recovery by attending to the minute histology of the blood and, finding an undue

eosinophile count of leucocytes, be led to the discovery of ankylostomiasis. The author says that since the study of botany has been neglected in the medical curriculum there has been, he believes, a loss of discriminative power in the student, and less ability for accurate differentiation in common observation. More botany and careful study of the materia medica, with more assiduous observation of the action of our common remedies, and perhaps less of elaborate chemistry, would be a change for the better.

Münchener medizinische Wochenschrift, March 16, 1909.

Alcohol in Hunger.—Kochmann says that alcohol has been proved to be a foodstuff capable of making up for waste of carbohydrates or fats or of saving the waste of proteins. He has experimentally studied the question of the influence of alcohol upon starving animals, using rabbits for this purpose. He concludes that in appropriate dosage alcohol is capable of prolonging the life of starving animals. Large doses of alcohol, on the other hand, hasten the death of the animal. The favorable effects of alcohol must be ascribed to the sparing of proteid metabolism and the maintenance of water equilibrium of the organism. Under its influence the proteid content of the body is kept at the same level, while other tissue elements, less important to life, are used up in the metabolic processes. The unfavorable effects of large doses are due to an increase in the waste of proteids, those rich in sulphur being most affected. Large doses increase the diuresis, smaller doses lead to diminution in the amount of urine secreted. These results are applicable to the use of alcohol in human beings. Very large doses have a toxic action and must never be prescribed. Small doses are very beneficial in the treatment of undernourished individuals, such as those with high fever, those who are unable to take nourishing foods, and those who refuse food. Alcohol has the same effects in healthy human beings, not supplied with a proper amount of food, and may, therefore, be advantageously used in such circumstances in time of war, or on similar occasions arising in any form of sport.

Deutsche medizinische Wochenschrift, March 4 *and* 11, 1909.

Serum Diagnosis of Syphilis.—Lesser says that a positive result of the Wassermann reaction should always lead to the diagnosis of syphilis or to a well-founded suspicion that any obscure symptoms present are due to syphilis, if the presence of scarlet fever is excluded. The negative result, on the other hand, does not exclude syphilis. The reaction is usually positive in inherited syphilis and in paralysis due to preceding syphilitic infection; the former fact is of special value in diagnosing the nature of various affections of the special organs, such as the eyes, in childhood. Lesser has tried the reaction in over two thousand cases and reports the following figures: The reaction was positive in 69 per cent. of cases showing the primary lesion only, in 91 per cent. of the early period with symptoms, in 67 per cent. of the same period without symptoms, in 90 per cent. of tertiary stage with symptoms, in 46 per cent. of this stage without symptoms, in 56 per cent. of the cases of tabes dorsalis, and in all cases of general paralysis. The fact that the reaction is often negative in the primary stage excludes it as a means of differentiating between chancre and chancroid; in such cases the presence of spirocheta pallida is the best proof of the nature of the lesion. The discovery of this organism and of the reaction enables us to study the effect of removing the primary lesion before the secondary symptoms appear; in two cases proved syphilitic by the finding of *Spirochæta pallida*, Lesser removed the primary sore, but this did not prevent the appearance of secondaries and of the reaction. Further study of this important question is needed. The outcome of the reaction is especially valuable in the numerous cases in which the infection is denied and yet many lesions suggesting syphilis are present. Such cryptogenetic syphilis is often proved by the positive reaction. The fact that general paralysis has always given a positive reaction shows that syphilis is the cause of this condition; the negative outcome in many cases of tabes dorsalis, on the other hand, simply shows that the luetic infection which may have existed has been completely conquered, though the anatomical changes in the cord remain. The positive reaction may be made to disappear by an energetic specific treatment, and this fact speaks strongly for the conclusion that such reaction means the existence of active syphilis; the latter may be manifested only by some changes in internal organs without leading to recognizable external signs or symptoms. The presence of the reaction, then, speaks for the necessity of continuing the treatment for active syphilis, however little manifestations of the disease may exist.

Clinical Value of the Wassermann Reaction.—Blaschko says that neither the fact that Wassermann reaction may be obtained in certain diseases, such as frambesia, sleeping sickness, and scarlet fever, as well as in syphilis, its clinical value is but little modified by this fact. Scarlet fever is easily distinguished from syphilis, while the other diseases are very rare in Europe. Blaschko reports his experience with one thousand patients, in whom the reaction was tried. In over thirty cases the reaction was negative, though the diagnosis of syphilis could be made on other grounds; tabes dorsalis and syphilitic disease of the bones were most frequently represented among these negative results. Blaschko has also observed ninety cases in whom a strong positive reaction was changed by thorough antiluetic treatment into a weak reaction, or was made to disappear altogether. The diminution in the intensity of the reaction ran for the most part parallel with the disappearance of clinical symptoms. In general, it is wise, therefore, to continue treatment until the reaction disappears, though cases may be met with to which this general rule cannot be applied. The other question, whether the mere presence of a positive Wassermann reaction should serve as an indication of treatment, ought to be answered in the affirmative at present, for such a reaction is really a symptom of syphilis, with the exception, of course, of cases of scarlet fever, etc., in which the reaction may also be seen. So far as the value of the reaction for prognosis is concerned, Blaschko's conclusion is that a persistence of the positive reaction in the first three years of syphilis is not to be taken as an unfavorable sign; the disappearance of the reaction in the same period, on the other hand, must not be taken as a favorable sign. The outcome of the reaction becomes of prognostic importance only in the later stages of the disease, when persistence of a positive result must be looked upon as indicating incomplete success of treatment or the development of post-syphilitic affections. In general all conclusions as to Wassermann reaction must at present be only tentative; it is the duty of sphilidologists to make use of their material in the study of the reaction so that more dependable judgment may be soon had in reference to the value of the reaction.

Disinfection in Gynecology Without Soap and Water.—Otto v. Herff says that the principle of the disinfection used by him is not to soften the skin and thus not to bring out the germs hidden in its deeper layers. Only the germs on the surface of the skin are dangerous and they must be surely destroyed. The usual technique of disinfection with the use of soap, water, and brush simply uncovers the organisms that otherwise lie latent in the skin. Herff begins the preparation of the skin on the day before operation by giving the patient a bath and by removing the hair from the area to be prepared, the razor and a depilatory powder being used. A wet dressing that is often used in preparing the field of operation simply renders the skin a good culture ground for the growth of bacteria. Then after anesthesia has been begun the field is wiped for four minutes with 50 per cent. alcohol acetone; then the alcohol is removed by rubbing the skin for one minute with pure acetone, and the skin dried by sterile gauze. After the operation the field is wiped dry, but not washed. Acetone is the special agent in this method, for it acts as a solvent of fat and at the same time removes most of the moisture from the skin. In order that the surrounding tissues may be protected from secretions of the wound, alcoholic tincture of benzoin is applied. The entire technique is very simple and therefore well adapted for emergency preparations. The results in over three hundred cases show that the omission of the soap, brush, and water has led to no increase in general or local infections after operation.

The Placenta of Eclamptics.—A. Brindeau and L. Nattan-Larrier describe the lesions found by them in the placenta of eclampsia, of albuminuria of pregnancy and retroplacentar hemorrhage. There is a typical form of placenta found in these conditions and there is a less complex form of lesion. The typical form includes nodular infarcts, arteritis, endometritis, edema, and small hemorrhages. This corresponds to slow formation. In the second form there are diffuse hemorrhages, rupture of fetal vessels, and plasmodial proliferation. These occur rapidly in cases of sudden convulsions.—*L'Obstétrique.*

Book Reviews.

Diseases of the Digestive Canal (Esophagus, Stomach, Intestines). By Dr. Paul Cohnheim, Specialist in Diseases of the Stomach and Intestines in Berlin. From the Second German Edition. Edited and Translated by Dudley Fulton, M.D., Lecturer on Medicine, University of Southern California, Los Angeles. Illustrated. Philadelphia and London: J. B. Lippincott Company, 1909.

The author explains the addition of another volume to the large number of special treatises on gastrointestinal diseases as due to the fact that he has written for the general practitioner, and inasmuch as his practice has always been a general one, he believes himself qualified to understand their needs and opportunities. His text proves his reasoning to be correct, for throughout the work he has been clinical in his point of view, in his diagnosis, and in his treatment. To make the book one of moderate size he has omitted the physiology, pathology, and anatomy of the subject and has plunged at once into the practical discussion of sick patients who are seeking an opinion and relief from symptoms. Unlike so many specialists he seeks to minimize the need of laboratory help and shows how the history, if complete, is the great means toward a diagnosis if properly understood. To make the reader a good historian is evidently his aim, and in this he excels; each clinical point of importance is emphasized, and its significance, whether great or little, is taught directly and unhesitatingly. His use of words is careful, and he adopts such terms as "epigastric pain" as signifying a pain of an unexplained origin but fairly definite location. The author's view of surgical interference, for instance, in gallstones and in appendicitis, is extremely conservative, more so than is the stand taken upon these subjects by American surgeons, but aside from this the treatment advised is such as the modern advanced internist who is no faddist or theorist would be apt to employ.

Practical Dietetics. With Reference to Diet in Disease. By Alida Frances Pattee, Graduate, Department of Household Arts, State Normal School, Framingham, Mass.; Late Instructor in Dietetics, Bellevue Training School for Nurses, Bellevue Hospital, New York City; Former Instructor at Lakeside, St. Mary's, Trinity, and Wisconsin Training Schools for Nurses, Milwaukee, Wis.; St. Joseph's Hospital, Chicago, Ill.; Special Lecturer at Bellevue, Mount Sinai, Hahnemann, and the Flower Hospital Training Schools for Nurses, New York City; St. Vincent de Paul Hospital, Brockville, Ontario, Canada. Fifth Edition. New York: A. F. Pattee, 1909.

This well-known book, which has reached its fifth edition within six years, can be recommended as of great value to those who have to prepare food for the sick. Innumerable recipes for various dishes, enemas, etc., and the special diets suitable for certain diseases make up a volume which no nurse could afford to do without. The second portion, "Diet and Disease," is wisely taken from the writings of physicians who are authorities and can be thoroughly trusted.

Indications Opératoires dans les Affections de l'Estomac. Par Dr. A. Delangre. Paris: Vigot Frères, 1909.

Delangre's work on the indications for operations in affections of the stomach is very timely. The material is grouped in a systematic way, and is very instructive.

Delangre advocates surgical intervention when there are strong indications for such a procedure, otherwise he recommends rational medical treatment. Thus he says (p. 61): "In fact pure gastrosuccorrhea of a spasmodic nature ought to be treated internally only: absolute milk diet in conjunction with belladonna ought to be prescribed in every instance. It is not quite the same in gastrosuccorrhea with food remnants; in the presence of the latter in the stomach, due to stasis, gastroenterostomy is indicated, as this condition, if left untreated, will cause dilatation of the stomach. Medical treatment and a postoperative diet of fat and vegetables must then be strictly followed by the patient in order to permit the '*restitutio ad integrum*.'"

In acute gastric hemorrhages Delangre prefers medical treatment. He expresses himself as follows (p. 77): "In the majority of cases of sudden, severe hemorrhage, operative intervention has been connected with direful results for the patient. In spite of several rare and lucky operations, such as that of Rossoni of Rome, where surgical intervention was successfully practised, based on the indication of a very severe hemorrhage, and revealed the presence of a small ulcer seated over a small artery that could be ligated, abstention should be the rule in large hemorrhages. The large incision into the stomach and its internal exploration constitute a very serious intervention for a run-down patient of low resistance, especially as the checking of the hemorrhage is not always such a simple maneuver. Firstly, the bleeding ulcer is at times difficult to locate, as was proved in Hartmann's case, who was able to find the erosion only after the minutest examination on the autopsy table; secondly, the ulcer is at times adherent and difficult of access, or the infiltration of the tissues prevents the proper placing of a ligature. Thus the deplorable results of operations during a hemorrhagic crises may be explained."

In dilatation of the stomach Delangre advocates an operation if there is ischochymia present, which latter is usually due to pyloric stenosis. He agrees with Hartmann that operation for atonic dilatation is only exceptionally indicated, and that the knife has been used too much in this condition, instead of insisting on medical treatment, which is well understood and must be sufficiently prolonged.

In simple dilatation, so common in practice, the stomach empties itself during the night. General as well as local medical treatment will frequenty cure this condition. Therefore Delangre has but little confidence in gastrorrhaphy or gastroplication by means of folds and sutures on the anterior surface of the organ. As a whole, the book can be highly recommended to physicians and surgeons alike.

Selected Bibliography of Sanitary Science and Allied Subjects. Prepared by Arthur W. Smith, M.A. (Yale), for the Use of Classes in Sanitary Science in the College of Liberal Arts, University of Colorado. Boulder, Col.: A. A. Greenman, 1909.

This is a usable bibliography because well annotated. There are 420 titles, including articles in periodicals and chapters in books. These are arranged alphabetically by authors under the following headings: General Works on Sanitary Science; General Hygiene, Personal Hygiene, School Hygiene, Etiology of Disease, Bacteriology, Protozoology; Infection: Means, Vehicles, and Carriers; Immunity: Toxins, Antitoxins, Opsonic Method; Disinfection and Disinfectants; Water, Milk, and Food; Sewage Disposal and Purification; Climate and Health, Geography of Disease; Heredity, Race Improvement, Degeneration, Old Age; Vital Statistics; Patent Medicines, Quackery, Medical Superstition; Specific Infectious Diseases; Relation of Government to Sanitary Science; Public Health Administration.

Industrial and Personal Hygiene. By George M. Kober, M.D., LL.D.; Chairman of the Committee on Social Betterment of the President's Homes Commission; Professor of Hygiene, School of Medicine, Georgetown University. A Report of the Committee on Social Betterment. Washington, D. C.: Published by the President's Homes Commission, 1908.

This is a timely pamphlet on the subject of industrial hygiene. Since health is the chief asset of the workingman, anything that tends to the preservation of his health must necessarily be an economic factor of the first importance. In this *brochure* will be found a considerable amount of information on almost everything appertaining to the subject. It is well written, in simple language, and should prove of much service. The few pages at the end, on personal hygiene, are brief and sketchy, and are not of the same value as the rest of the volume.

Blood Examination in Surgical Diagnosis. A Practical Study of Its Scope and Technique. By Ira S. Wile, M.S., M.D. New York: Surgery Publishing Company, 1908.

This is an elegant little volume dealing with the changes met with in the blood in various surgical conditions. The subject is treated not from the theoretical standpoint, but from the viewpoint of practice, the means of examining the blood, and the conclusions that can be drawn from such examinations being concisely given. The author has done a great deal of hematological work for large hospitals, and writes from his own experience rather than from a study of hematological literature; his methods and conclusions have been tested in practice and are the more valuable for that. We recommend this little volume without hesitation to the hospital internes engaged in doing much blood work, and to the young surgeon who does not want to miss the help in diagnosing disease which a study of the blood by modern methods can so often render. To the author we would suggest that the substitution of colored drawings of blood findings, using the colors obtained by the use of such stain as the Jenner, for instance, will greatly enhance the usefulness of the book; the black and white drawings do not give good representations of the stained blood films.

Society Reports.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held February 15, 1909.

The President, Dr. Robert T. Morris, in the Chair.

The Medical Importance of the Study of Anthropology.—Major Charles E. Woodruff, Surgeon U. S. Army, read this paper. He said that our expansion to tropical climates had taken soldiers into new environments, which had created an entirely new subject for sanitary investigation, namely, the relation of races and climates. One phase of this was the curious reduction of resistance which made all infections far worse in the tropics than in the normal environment. It had been found that some patients would not get well there at all, and that as a rule recovery in all cases was vastly hastened by sending the patient home. There was a constant stream of invalids sent home from all tropical climates, and, omitting a few dissenters, there was a generally accepted opinion that two years was the longest period it was safe to remain in hot places without more or less prolonged vacation in a cold country. Explanation of this failure to retain vigor when out of our usual environments was quite easy on general laws, but most difficult when we got down to particulars. While biologists for half a century had been talking about adaptation to environments the medical profession had completely ignored it, and the opinion was wide spread that the differences between types of men was of no significance whatever. Consequently, no investigations had been made. Unfortunately, all races of men had generally been considered to constitute one species, and there was once a prevalent notion that man was superior to the universal natural laws governing all other animals. Professor William Ridgeway of Cambridge had recently protested against the old idea of man's isolation from the rest of creation, and had pleaded for the view that we were governed by all the natural laws which modified other animals. One of the greatest obstacles to the determination of characteristics due to the selections of variations was the fact that a modification might appear generation after generation as long as the cause acted, though such acquirements were never hereditary. For instance, a race was forced into an inhospitable place, where sufficient food was not available, and at once they showed reduction of stature, which might last for centuries, as though it were an hereditary useful variation. Let them come to America, where the children could be well fed, and the latter at once grew to a much higher stature than their parents, thus proving that the low stature was not a specific character like that of tropical natives, but a mere acquirement sure to disappear with its causes. Another disturbing factor was the effect of use and disuse. On the other hand, pigmentation was a result of survival of favorable variations caused we did not know how, for sunburn was never transmitted. Why was there such a great tendency to shortness of stature in the tropics and great tallness toward the colder places? Heavy northern men did not stand the tropics as well as the little ones, and the speaker said he had been struck by the fact that men of short stature, particularly those of the brunette type, often enjoyed the Philippine climate, and that the big men, with some exceptions, labored under it. Heavy men had less radiating surface than thin men of equal height. Bulkiness was a decided advantage in retaining body heat in cold climates, but it prevented sufficient radiation in the tropics, so that the disturbances of body temperature broke down the nervous system in the course of some years. Another character which had long been noted as varying with the climate was the nasal index, or the width of the nose divided by the length. This index was smallest in cold climates and largest in the tropics, where the width might even exceed the length. This had no fixed relation to the size of the nose, but there had long been an hypothesis that it was related to the size of the nasal cavities, which were supposed to be larger in the tropics to admit more air.

In discussing the effect of light, Major Woodruff said it seemed that for the greatest efficiency we were dependent upon the stimulation of a small amount of light, and, though mere health was possible with very little, as in the case of miners and night workers, yet total deprivation, as in the Arctic winters, was decidedly depressing. On the other hand, light in large amounts was invariably lethal, and even in smaller doses, it might be unduly stimulating, so that the limit of safety was far below the point generally accepted by the medical profession. Consequently, nature was always at work removing the specimens insufficiently protected, so that in the course of time the people in certain localities became pigmented in proportion to the maximum intensity of the light, irrespective of the temperature. The negro's skin did not keep out all the light of the tropical sun, but so far as we knew it transmitted about as much as passed through the skin of a blonde in the feeble light of cloudy places in Europe. The evidence was fairly conclusive that blonde races disappeared when they migrated to lands of excessive sunshine, but they survived longer if the light was less intense. A careful investigation of several regiments in the Philippines some years ago showed that even in the short time of two years the blondes had a higher morbidity and a much higher mortality rate than the brunettes. The statistics already available (*New York Medical Journal*, Sept. 12, 1908) showed that blondes furnished more cases of tuberculosis than brunettes in this country, and had a quicker mortality of the infected. The rapidity and malignancy of the disease among blonde immigrants from Scandinavia and Ireland and blonde Jews was now a matter of record, and was the same phenomenon as the awful rapidity of the disease among white people in the tropics. It was well known that certain cases of tuberculosis did not improve in our northern mountains. What types were they? A few years ago we were all convinced that light in unstinted amounts was essential in treating tuberculosis, though a goodly number of men were now convinced that it was of very minor importance, and a still larger number were discovering facts which proved that in large amounts it was harmful. In the Philippines, where we had unstinted sunshine even in the rainy season, the disease was rapidly fatal, while in very cloudy places it was quite curable. There was no perfect climate for any disease excepting the one by which the patient's physique was evolved. In sending invalids away in search of health we must consider each individual far more than we had done in the past.

Dr. Livingston Farrand, Professor of Anthropology in Columbia University, said that while he did not feel qualified to speak on the special relation of anthropology to medicine, as he had not given that phase of the subject particular attention, still, there was one lesson that he had learned from a general study of anthropology, and that was, extreme caution. If there was any branch of human knowledge along which we had to proceed cautiously, it was in this particular field. There were few lines of investigation in anthropology where our statistics were sufficiently complete to permit us to generalize freely, and there was no field in which our preconceptions had to be so often abandoned as here. Dr. Farrand said nothing definite was known about the effect of light on different races and individuals, and he could only second Major Woodruff's plea for more careful observation and detailed knowledge on that point. It was highly desirable that we should obtain more accurate clinical observations from which to

draw conclusions. The term "race," to which we so freely referred, was one that had fallen into hopeless disrepute. It was questionable whether such a thing as a race still existed. In deciding this we had no criteria to go by, and we could not even agree as to which were the great races, so called. To-day there was a tendency to classify the human family into two races, viz., the negroid, or black, and the mongoloid, or yellow. Of these the former was the more permanent type, yet even in that we found every possible modification in stature and color in different parts of the continent of Africa. We did not know whether white was a modification of the yellow or of the black. Europe was occupied by a perfect hodgepodge of "races," and even in Africa we had these variations which were obviously the result of generations of admixture. While as a rule the black or dark skinned races lived in the tropics and the light skinned races were found further north, yet there were many puzzling exceptions to this rule in both hemispheres, *e.g.* the very light skinned Hottentot—Bushman group in South Africa. Still, we had to admit that as a rule the darker skinned races occupied the tropics. Before we could assert that this was due to the influence of light or to purely climatic causes we had to learn more about the genealogy of these people and how they happened to be there. The teaching of anthropology, based upon recent investigations, had tended to show a general uniformity of the human race in its various characteristics, and that the variations between different so-called "races," both physical and mental, were much less marked than we formerly supposed them to be. The physical modifications, to some of which Major Woodruff referred, were extremely slight. Referring to nervous derangements in primitive races, to which subject Professor Farrand said he had given some study, the speaker said that his investigations did not bear out the oldtime belief that insanity was largely a product of civilization. The untutored savage, who had never been subject to the pressure of civilized life, was probably the most hysterical individual in the world, and was apparently subject to nervous derangements to just about the same degree as the whites.

Dr. Woods Hutchinson said that Major Woodruff had called attention to one of our pet delusions, namely, that sunshine was such a good thing that we could never get too much of it. The majority of us believed that if a moderate amount of sunshine was good, more of it was better, and in consequence we had used it and abused it. The speaker said he had lived for a time in northern Oregon and Washington, where for a large part of the winter the weather was cloudy and misty, but occasionally, with a breeze from the desert to the northeast, the sun would come out, and at those times the old residents would begin to complain of colds and catarrh, and claimed they did not feel well. In southern California, particularly in the region of Los Angeles, the land of perpetual sunlight, the northern immigrant was perfectly delighted with the climate during his first summer. During his second season he was not quite so enthusiastic, and when his third season there arrived he was very apt to go up into the mountains or down to the seashore, where the fogs and rain gave some relief from the everlasting sunshine. The continual dazzle and glare of the sun grew more monotonous than did the fog and the rain. Dr. Hutchinson said he agreed with Dr. Farrand that we should be cautious in drawing any conclusions on this subject until we had collected more data upon which to base them. As yet we did not know what constituted a race. The so-called "racial characteristics" by which a race was recognized were often distinctly rare, even in that particular race. For example, the "almond-shaped" eye was found in only about ten per cent. of Mongolians. If we took any race and examined it as to the number of vivid, striking blondes we would find them far outnumbered by persons of intermediate coloration, and the same was true of the brunettes. The vast number of people were—not black and tan, but a combination of the blonde and the brunette. Most races of blondes had only about ten per cent. of real blondes among them. We of the so-called white race, while forming only a small minority, were a set of "sports" in the biological sense, and the race owed its dominance to its faculty of adjusting itself to the environment in which it was placed. It possessed this power of adjustment to a striking degree. In referring to the uncertainty of our knowledge in regard to so-called racial immunity, the speaker called attention to the exploded theory that the negro was immune to malarial infection. Pigmentation of the skin might possibly be simply associated with some other peculiarity in the individual and be of direct value in itself. Practically, blondes were as a rule tall, while nearly all short races were dark, and the disappearance of the pigment in these blonde races might be merely a concomitant of increased height. Because pigmented races lived in the tropics that did not prove that the pigment was necessary to their existence there. We were not yet in a position to say that such a pigmented condition was either necessary or desirable for persons who were obliged to live in the tropics. White races did not do well in the tropics, but they did far better than negroes, and had lower death rates, higher birth rates and higher longevity. The real immunity was that which was built up by generation after generation of exposure to infections. That, in the speaker's opinion, was the principal factor in racial immunity and more important than color or anything else.

The discussion was continued by Drs. Charles A. Leale, John Herman Branth and the president, Dr. Morris, and was then closed by Major Woodruff.

The Value of the Mixed Toxins of Erysipelas and Bacillus Prodigiosus in Inoperable Sarcoma, Based Upon a Study of Cases Treated During the Past Sixteen Years.—Dr. William B. Coley, in this paper, said that while the results of this treatment had not been as satisfactory as one who was seeking for perfection could wish, they had been sufficiently real and tangible, he thought, to be entitled to more careful consideration than they had yet received. Furthermore, they might have an important bearing upon the whole cancer problem, since, if by the administration of certain bacterial toxins we could cause the degeneration, death and absorption of living tumor cells of one variety of cancer, *i. e.*, sarcoma, it was not unreasonable to suppose that by the use of some other forms of bacterial toxins we might succeed in destroying or inhibiting the growth of the other and more common variety, namely, carcinoma. The speaker emphasized the statement that the method rested upon a solid foundation of accepted and indisputable clinical facts, namely, that in a considerable number of cases of inoperable cancer of all varieties, and especially sarcoma, such tumors had been known to entirely disappear under attacks of accidental erysipelas, and patients had remained well for many years thereafter, and during the past two years, at the Huntington Cancer Research Fund, Dr. Martha Tracy and Dr. S. P. Beebe had shown that large multiple sarcomas in dogs rapidly disappeared under local or systemic injections with the mixed toxins of erysipelas and bacillus prodigiosus. Dr. Coley believed that the following were the indications for the use of the mixed toxins: 1. In all cases of inoperable sarcoma, excepting the melanotic, which were probably of epithelial origin. 2. In cases of sarcoma originating in the long bones, in which operation meant the sacrifice of the limb. 3. Immediately after operation (within a week or two) in all primary inoperable cases, as a prophylactic against recurrence. 4. In addition to the foregoing, after primary operations for carcinoma as a prophylactic against recurrence. The use of the toxins as a prophylactic after operation he believed offered by far the

most important field of all, the proportion of recurrences in his own experience thus far being less than 25 per cent., whereas in cases in which the toxins were not used after operation the proportion of recurrences had been fully 75 per cent. As regarded the dangers from the use of the toxins, he stated that personally he had found their administration practically free from danger. However, he had learned of several fatal cases in the hands of other men, which, taken together, showed that there were certain risks connected with the treatment. He believed, however, that if the precautions he had always made it a point to emphasize in former papers were observed, these risks would be reduced to a minimum. Most of the fatal cases that had occurred had been due to a neglect of those precautions. Dr. Coley said that up to the present time he had 51 cases of inoperable sarcoma successfully treated with the mixed toxins of erysipelas and bacillus prodigiosus. Of these, 35 had remained well from 3¼ to 16 years, 14 from 10 to 16 years, and 28 from 5 to 16 years. To the 36 successful cases published by him in the *American Journal of the Medical Sciences*, in March, 1906, he had since added 15. In the first 36 cases there was, in addition to the tumors being adjudged inoperable by leading surgeons, a careful microscopical diagnosis made in all but two instances. In connection with his paper Dr. Coley presented eight patients upon whom the treatment had been successfully used.

Dr. Howard Lilienthal, discussing Dr. Coley's paper, said that under the use of the mixed toxins he had seen cases of sarcoma get well in which, without this treatment, he was confident death would have occurred. He recalled one case of inoperable giant-celled sarcoma of the ribs and pleura which disappeared under the use of Coley's fluid, and the patient remained free from recurrence for a period of eight years. Recently he had returned complaining of pain at one end of the cicatrix, which disappeared promptly upon resuming the use of the toxins. Dr. Lilienthal said he had frequently employed the serum as a prophylactic measure, and thus, he firmly believed, prevented a recurrence in cases where it could otherwise have been confidently looked for. He advocated its use not only in inoperable cases, but also in operable cases as a prophylactic measure.

Dr. William Seaman Bainbridge, in discussing Dr. Coley's paper, expressed his appreciation of the opportunity of seeing the interesting cases presented. He had come to the meeting to listen and learn, with no thought of taking part in the discussion. Since the chairman had called upon him, however, he would say that for ten years or more he had been especially interested in the study of cancer, particularly sarcoma, with reference to finding some successful non-surgical method of treatment. He had, therefore, read with great interest the various reports presented by Dr. Coley and others concerning the mixed toxins, and had himself for some time been collecting data upon this subject. While he had endeavored with reference to this, as with all things else, to maintain the scientific attitude, which calls for the proving of all things and holding fast to that which was good, he regretted his inability to voice the implicit faith in the efficacy of this method to which Dr. Coley had given expression. He was surprised to hear the claim made that the almost universal skepticism which he had noted both in America and in Europe was so fast being dispelled. Like many others, he was earnestly seeking after truth, and would welcome more conclusive proofs of the final efficacy of the mixed toxins than even the interesting cases presented this evening seemed to furnish.

Dr. Coley, in closing, said he now advised the use of the toxins after operation in every case of cancer as a prophylactic measure. For that purpose he gave small doses, only sufficient to bring the temperature up to 99° or 100°, three times a week, and continued for five or six weeks. If this method were generally adopted he believed that we would see fewer inoperable cases. The skepticism in regard to the value of the treatment, to which Dr. Bainbridge had referred, had markedly diminished, especially during the past year. It was now employed by very many prominent surgeons throughout not only America, but Europe. At the Mt. Sinai Hospital, in New York, Dr. Gerster and Dr. Lilienthal had adopted it, not only in inoperable sarcoma, but far more important as a routine treatment after all operations for primary sarcoma as a prophylactic against recurrence.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held March 5, 1909.

Dr. Ellsworth Eliot in the Chair.

Nephrectomy for Twisted Pedicle.—Dr. C. Putnam presented a woman who at operation was found to have a kidney the size of a large orange, with a twisted pedicle. After being in bed for several days with high temperature and symptoms of collapse, a nephrectomy was performed. The pathologist found the mass to consist of multiple miliary abscesses, due to the shutting off of the blood supply by the twisted pedicle. The woman made a good recovery.

Nephrectomy for Tuberculosis.—Dr. C. Putnam presented a woman who had been run into by a bicycle and had received a severe blow in the side which rendered her unconscious. A short time after this accident blood appeared in the urine and a year and a half ago she had an attack of appendicitis, which she said "cured" the hematuria. The bleeding, however, appeared later, and three or four months ago a cystoscopic examination revealed a patulous ureter with tuberculous ulcerations about the vesical orifice. A nephrectomy resulted in the complete cure of the hematuria.

Intestinal Obstruction from an Adhesion of a Loop of the Ileum to a Tuberculous Mesenteric Gland.—Dr. W. S. Schley presented a patient who had been admitted to the hospital three years ago with a typical attack of acute intestinal obstruction. There was a history of cramp-like pains in the abdomen at intervals of a month or two for a year past. The large intestine was found to be completely collapsed, while the small intestine was distended. The obstruction was found to be caused by an adhesion of a loop of the ileum to a tuberculous mesenteric gland. The gland was yellow in color and cheesy, and was apparently an old tuberculous gland. The patient gave no other history of tuberculosis.

Large Carbuncle of the Neck; Cosmetic Result After One Year.—Dr. W. S. Schley presented a man who had a large carbuncle of the neck. The motions were now entirely normal, and the cosmetic results were perfect.

Appendicitis with Perforation of an Enterolith, Following Typhoid Fever.—Dr. S. Minot Milliken presented a man, twenty-two years of age, who had entered Lincoln Hospital June 4, 1908, and whose case had been diagnosed as typhoid fever. He did not look very ill, having a temperature of 101°, pulse 102, and respirations 24. The white blood cells numbered 6,000 and there was 72 per cent. polynuclears. The diazo reaction was present. This patient ran a low grade of typhoid fever for seven days, when his temperature rose to 101° and his pulse to 88. Later that day his temperature went to 102.6°, pulse to 120, and a diagnosis of perforation was made. When Dr. Milliken saw the patient, he had a rigid abdomen and exquisite tenderness to even the slightest touch over the right lower left quadrant. There was flatness in the right

flank. At operation edema of the peritoneum was found and a cloudy serum escaped from the peritoneal cavity when that was opened. There was no perforation of the small intestine, but an abscess was found about a retrocecal appendix. A gangrenous appendix was found perforated just beyond the middle. In the bottom of the abscess cavity an enterolith was found the size of a grapefruit seed, which was composed of dry fecal matter, and was very friable. A fistula persisted after the operation, which rapidly closed except for a small tract which persisted for another week. A week after the patient left the hospital this fistula reopened and remained so for a time and finally the man was brought back to the hospital with all the symptoms of acute obstruction. He was immediately operated upon, and the cause of the obstruction was found to be a fibrous adhesion extending from the mesial side of the cecum to the left leaf of the mesentery and firmly binding the small intestine to the abdominal wall. The division of this band released the obstruction. The fistulous tract was found as a small cord leading from the upper surface of the cecum well above its blind end. The patient made a good recovery. In his opinion the presence of the fistula was due to the pressure of drainage tubes on the inflamed surface of the cecum where they crossed to come through a wound distant from the abscess cavity. The occurrence of an enterolith in the appendix, causing a perforation after typhoid fever, made the diagnosis obscure, and seemed such an unusual complication that the case seemed worth while reporting.

Large Submucous Lipoma of the Ileum, Producing a Chronic Ileocecal Intussusception Intermittently Protruding at the Anus; Laparatomy; Resection; Recovery.—Dr. DeWitt Stetten presented this patient, who was admitted to the German Hospital with the diagnosis of rectal prolapse. She was thirty-six years of age, and had suffered from the prolapse for two years She had also suffered from constipation and flatulency. There was no blood or mucus in the stools, and the patient had not lost in weight. Abdominal examination revealed an indistinct, soft, nonsensitive, movable mass in the left hypochondrium. The rectum was dilated, but there was no prolapse. After the administration of a cathartic and during defecation a mucous membrane covered mass, the size of a large fist, was extruded at the anus; it was lobulated and apparently had no lumen; it had a long, thick pedicle running high up into the sigmoid, so that the end could not be reached with the examining finger. The mass was replaced with difficulty, and the abdomen reexamined. The indefinite abdominal tumor seemed somewhat lower than at the first examination. A presumptive diagnosis of polyp of the sigmoid or descending colon with partial invagination of the wall of the gut was made. At operation a dilated but empty sigmoid and descending colon were found. In the left half of the transverse colon a soft movable mass was followed to what seemed to be the ileocolic junction. An ileocecal invagination existed, and an attempt was made to disinvaginate this, which was but partially successful. About 2 cm. of the invagination was reduced, leaving the invaginated mass extending to the hepatic flexure. Diagrams were shown illustrating these points. It was found that further attempts in this direction would be futile and resection, according to Maunsell's method, was decided upon. The appendix was removed, the colon opened longitudinally, and the mass delivered and resected at its base. The patient made an uneventful afebrile recovery. The wound healed primarily. The specimen proved to be a lobulated submucous lipoma of the lower ileum at the apex of the intussusception. A search of literature showed that nearly eighty cases had been reported. The submucous lipoma was a comparatively frequent form of so-called benign intestinal neoplasm. In nearly one-third of the recorded cases an acute or chronic invagination was the result of the presence of a tumor. A large proportion of them terminated fatally.

Pelvic Ureteral Calculus in the Female, with Special Reference to the Operative Method.—Dr. A. Isaacs said that during the past year he had seen four women who had been operated upon for ureteral calculi, and the stone in each case was situated very low in the pelvic portion of the ureter. Although calculi might become impacted in any portion of the ureter, there seemed to be points of election. Morris gave three of these: first, one or two centimeters below the commencement of the ureter; second, where the ureter crossed the brim of the bony pelvis; third, at the intramural portion of the ureter where it passed between the coats of the bladder wall before entering. The method of operation depended to a great extent upon the location. According to all accepted authorities he should have made his approach from below, but it seemed to him that he could work down from above more easily, in spite of the anticipated difficulties. The peritoneum was raised from the pelvic wall, after the usual incision had been made, and the iliac vessels were exposed; the ureter was located upon the raised peritoneum, and in its exposed portion was separated from it, and a traction strip passed around it to draw it up out of the pelvis. At the base of the broad ligament it was very adherent. Probably one inch or more of the ureter distal to the point of separation, together with its adherent and surrounding structures, could be picked up between the thumb and fingers and palpated to find if it contained a stone. The traction from above was of material assistance in permitting this to be done. In all four cases the stone laid beyond the uterine artery, and milking the stone backwards and proximally to the artery eliminated the necessity of its division and ligature. The inguinal retroperitoneal operation was practical and fairly easy of accomplishment when the calculus was as low down as one and one-half inches from the vesical orifice. When in the intermural portion of the ureter the stone might be more easily removed transvesically.

Metastatic Hypernephroma of the Serratus Muscle.—Dr. J. Hitzrot presented a man, fifty years old, admitted to the hospital on January 28 with tumor of the right shoulder region. The tumor was elastic, not hard, and appeared as if under the latissimus dorsi muscle. The pathologist stated that the tumor was a hypernephroma. It was found to involve the entire serratus magnus muscle. The cystoscopic examination showed the urine coming from the left kidney to be slightly cloudy; whether urine came from the right kidney or not could not be determined. At present the patient had a tumor of the right side distinctly palpable. All the long bones had been *x*-rayed but no metastases were found. There were, however, metastases on the right side of the chest. This was the first case in which such a metastasis was found in the muscle.

Hemorrhagic Cyst of the Liver.—Dr. Hitzrot presented a man, thirty-two years old, who had had alcoholic gastritis a number of times and had passed blood per rectum. He had had his right side severely injured. The skin became shiny and some swelling appeared over the injured area. He vomited and passed a great deal of blood per rectum. A needle was inserted into this swelling and blood was withdrawn, eighty-two ounces having been withdrawn by means of a suction bell. This was a hemorrhagic cyst of the liver, and recovery followed.

Acute Pancreatitis.—Dr. Ellsworth Eliot presented a patient, thirty-three years old, who had had several attacks of indigestion during the past year. The last attack occurred eight weeks ago, and there was slight jaundice with it. Thirty-six hours before admission to the Presbyterian Hospital the patient was seized with

sharp, lancinating pains in the left epigastrium, passing anteroposteriorly into the back. Examination showed the abdomen not distended, tympany about the umbilicus, auscultatory dullness in the left flank and slight in the right, rigidity over the entire abdomen, tenderness just above and to the left of the umbilicus. The temperature was 102°, pulse 120, white blood cells 19,000, and polymorphonuclears 87 per cent. A serous, sterile, odorless fluid was found in the general abdominal cavity. The gastrosplenic omentum was oval, and an area of two by one inches was studded with nodules of fat necrosis. The tail of the pancreas was swollen and in the lesser cavity were several drams of clear sterile fluid. The head of the pancreas was found adherent to the greater curvature of the stomach, thus obliterating the right extremity of the lesser cavity. After a somewhat disturbed convalescence the patient made a good recovery.

Chronic Pancreatitis.—Dr. ELIOT also presented a man, twenty-nine years old, with a negative family history. He had had malaria, and for the past eighteen months had attacks of epigastric pain and vomiting; these attacks lasted several days, but the patient felt well between them. He had anorexia for five weeks, but no blood was vomited, and there was no jaundice. The physical examination showed the sclera distinctly icteroid. The liver dullness extended from the fifth space in the midcostal line to eight inches below the costal margin in the same line. The abdomen was a little prominent in the right upper quadrant. During the seven days the patient spent in the medical ward his temperature ranged from normal to 100.2°, pulse 60 to 72, and respiration normal. The Cammidge reaction was negative; the urine showed at one examination .6 per cent. sugar, at a second .2 per cent., and at a third none. At operation the gall-bladder was found to be adherent to the surrounding structures and to contain thick, dark material which proved to be sterile. The head of the pancreas was found to be much thickened, nodular, and hard. There were no stones, and the gall-bladder adhesions were separated and the ducts explored for stones. Since the operation the patient had not been jaundiced, felt well and strong, and had no distressing symptoms.

Etiology and Pathology of Pancreatitis.—Dr. E. OPIE said that the changes found at autopsy in this condition were not less surprising than its sudden onset and turbulent course. Hemorrhagic pancreatitis was recognized about fifty years ago. The classification of acute pancreatitis was almost universally adopted from the time of the Middleton-Goldsmith lecture of Dr. Reginald Fitz, which was delivered before the New York Pathological Society about twenty years ago. Recent studies had shown that the disease could be reproduced in lower animals by a variety of means. Some of these were the injection of bile into the pancreatic duct and the injection of gastric juice through the opened duodenum into the pancreatic duct. Duodenal contents had also been employed. Flexner had produced the lesion with weak solutions of a variety of acids and was equally successful with sodium hydroxide. There seemed to be no common character of these substances except their power to injure the tissues with which they came in contact. Acute hemorrhagic pancreatitis produced in these ways might be wholly unaccompanied by bacterial infection. There had been much discussion as to the relation of hemorrhage and inflammation. Did hemorrhage occur as the result of inflammation or *vice versa?* The study of the experimental lesion had shown that both hemorrhage and inflammation were secondary to necrosis of the parenchyma. The experiments of Flexner and others had demonstrated the surprising rapidity with which the change occurred, and this explained the sudden onset of the disease. Necrosis of the walls of the blood-vessels explained the multiple hemorrhages which characterized the lesion. Necrosis of the pancreas was usually caused by contact of some irritant substance with the cells of the gland. The peculiar necrosis which affected the pancreatic parenchyma was doubtless due to the trypsin which was obtained in the pancreatic cells. Recognizing the fact that necrosis of the tissue was the essential characteristic of acute hemorrhagic lesions explained the relation of hemorrhagic to gangrenous pancreatitis. Conspicuous symptoms of both human and experimental lesions were the profound intoxication, shock, and collapse of the circulatory system. Dr. Opie emphasized the following facts: (1) The pancreas was not more susceptible to spontaneous hemorrhage than other organs; so-called pancreatic apoplexy was an acute hemorrhagic pancreatitis. (2) Gangrenous pancreatitis was a late stage of hemorrhagic pancreatitis. (3) Hemorrhagic pancreatitis was not primarily the result of bacterial infection. (4) The most frequent cause of hemorrhagic pancreatitis was the penetration of irritant material into the ducts of the pancreas. Bile diverted by a gallstone lodged at the duodenal orifice of the common bile duct had produced the lesion in a large proportion of the cases. (5) Certain individuals were rendered susceptible to hemorrhagic pancreatitis by anatomical peculiarities of the pancreatic ducts.

Acute Pancreatitis.—Dr. JOHN F. ERDMANN read this paper. He said that the Cammidge reactions had proved very useful in diagnosis of this condition, especially when taken in connection with the history and other analyses jeopardize the patient's life. In this latter class of cases, in which the onset was very sudden and accompanied with intense abdominal shock; here the delay of from twelve to twenty-four hours needed to make the test would jeopardize the patient's life. In this latter class of cases, an exploratory operation was necessary to make the diagnosis. The difficulties of making a diagnosis in acute pancreatitis were multiplied by the contiguity of the pylorus, the gall-bladder and its ducts, and the head of the pancreas, which were so frequently invaded. The analysis of the stools had shown undigested muscle fibers. Fatty or oily stools were also evidences, as well as large, spongy stools. The urine frequently contained sugar, but he was inclined to think this a coincidence. The duct of Wirtsung was without question a very frequent source of entry for the infection. Gallstones, traumatism, alcoholism, and arteriofibrosis were also causative agents. Dr. Erdmann reported six cases which had occurred in his practice; four were hemorrhagic (two living), two had resulted in abscesses (one living). In one of the hemorrhagic cases the pancreas was almost completely destroyed. None of these cases was accompanied by sloughing, although sloughing was one of the terminations of an acute inflammation of this organ. Two of these cases were males, four were females, none were alcoholics, and none gave a history of syphilis. Two females were under thirty-three years of age and the remaining four were over forty years. The onset of the condition was usually sharp pain, a varying degree of shock, followed in some cases by profound toxemia, characterized by a peculiar cyanosis and lividity, with shallow breathing and rapid pulse. Hiccough was a symptom of relative frequency and persistence. There was vomiting and pain in the back. These symptoms, together with a history of previous digestive disturbances, and gall-bladder or duct invasion, should give great weight to the diagnosis of acute pancreatitis. Later a tumor might occur anywhere in the epigastrium. The subsequent manifestations were those of ordinary peritonitis. If in doubt as to the diagnosis, one should explore. If there was a peculiar bloody, beef-broth like serum or peculiar warty, yellowish-white plaques (fat necrosis) upon the mesentery, provided no strangulation existed, the search should be extended to the pancreas.

If an acutely hemorrhagic, enlarged pancreas was found an incision should be made in its peritoneal coat and a number of punctures made into the pancreas itself. Gauze should be placed in and about these punctured areas. In the six cases reported the gall-bladder was drained three times, each time for a large number of gallstones. Dr. Erdmann emphasized the necessity of early exploration when the set of symptoms described manifested themselves.

The Cammidge Reaction in Diseases of the Pancreas.—Dr. Francis P. Kinnicutt read this paper. (See page 589).

Dr. Robert T. Morris said that certain facts in connection with acute hemorrhagic pancreatitis impressed themselves upon one, many of them of considerable value, which could not be expressed in words.

Dr. Howard Lilienthal said that with their increasing experience with pancreatic affections, correct diagnoses were more often made. He thought it safer and wiser to make punctures, but not incisions, into the pancreas.

Dr. Samuel Lloyd said that the intense prostration, the vomiting, the restlessness, intense thirst, and other symptoms led to the recognition of the fact that they were dealing with some serious intraabdominal trouble which called for prompt action.

Dr. George Woolsey said it should be remembered that the vomiting in acute hemorrhagic pancreatitis did not relieve the pain, as it did in some other abdominal conditions. Some years ago he reported three cases in which he merely opened the abdomen, washed out the fluid from the abdominal cavity, and all the patients recovered without dealing with the pancreas at all. The Cammidge test was only applicable in the subacute cases. In the very acute cases operation alone would give relief.

Dr. Opie believed that their hope for recovery in these acute cases was in the natural processes of repair, the absorption of the necrotic tissue, and its replacement by scar tissue.

A Device for End-to-End Anastomosis.—Dr. A. Soresi made this presentation.

Pathological Society of Philadelphia.

At a stated meeting held March 11 Dr. John Speese exhibited a specimen of "Carcinoma of the Thyroid Gland." The organ was removed from a boy eleven years old, and on account of his age it was thought to be a sarcoma. Histological examination, however, disclosed the structure of carcinoma. Dr. David Riesman exhibited specimens from "A Case of Acute Miliary Tuberculosis with Perihepatitis and Large Fatty Liver." The patient was a woman with fever, delirium, enlarged liver, jaundice, tympanites, cough, expectoration, and a few tubercle bacilli in the sputum. Death occurred rather suddenly, and postmortem examination revealed a chronic tuberculosis of the lungs, with many miliary tubercles, and a miliary tuberculosis of the peritoneum, together with a greatly enlarged liver, the cells of which had undergone almost total fatty degeneration or infiltration. Dr. George Fetterolf exhibited "A Rare Anomaly of the Kidney." The specimen was obtained in the dissecting room from the body of an old colored woman whose left kidney was normal in all respects, but whose right kidney was in the right iliac fossa, with its hilum directed forward and its ureter passing over the ovarian artery. Dr John Speese exhibited for Dr. George P. Müller a specimen of "Ulcer of the Stomach" and one of "Carcinoma of the Gall-bladder." Dr Aller G. Ellis exhibited a specimen of "Tuberculous Ulceration of the Stomach." There was extensive ulceration of both small and large intestines, while a series of ulcers occupied the greater curvature of the stomach. Dr. W. M. Late Corlin demonstrated in himself a small excavated ulcer with indurated margins on the forearm induced by formic acid for the purpose of demonstrating the colloid basis of edema, and maintained by the application from time to time of artificial gastric juice. The lesion was supposed to indicate the mode of origin of ulcer of the stomach. Drs. D. J. McCarthy and H. T. Karsner presented a communication entitled "Report of a Case of Cystadenocarcinoma of the Thyroid Gland, with Remarks on the Pathology of Fat-formation." The specimen came from a case of adiposis, and it was used to illustrate the relations between the severe varieties of adiposis, that associated with pain, that attended with tumor-masses, and that of cerebral origin and associated with lesions of the generative organs. In most of the cases that have come to autopsy lesions of the thyroid gland have been found, and in some also lesions of the pituitary gland. Dr. Harlan Shoemaker read a paper entitled "Pseudoleukemia Gastrointestinalis." Dr. J. T. Rugh read the clinical account, detailing the case of a man 20 years old who presented enlarged glands in the neck and enlarged tonsils, with a considerable degree of anemia without change in the number of leucocytes, but with a relative increase in the number of lymphocytes. After death the small intestine was found studded with small leukemic nodules. Dr. Aller G. Ellis presented a communication entitled "An Experimental Study of Joint-affections Induced by the Typhoid Bacillus." He attempted to induce articular lesions by introducing typhoid bacilli into the blood serum and inflicting local traumatism, but, like other experimenters, he failed in this attempt. To bring about the desired result he was compelled to introduce the bacilli directly into the joint.

Philadelphia County Medical Society

At a stated meeting, held March 10, Dr. R. Max Goepp read a paper entitled "Remarks on the Administration of Sea-water by Subcutaneous Injection, with a Report of Cases." The water employed was obtained at some miles' distance from shore and from a considerable depth. It was diluted with fresh water to reduce it to the specific gravity of blood-serum, and it was then passed through a sterile Berkefeld filter. From one ounce to ten ounces or more were employed at each injection, the treatment being repeated on alternate days, and the fluid being introduced into the subcutaneous tissues of the buttock or the infrascapular region. The results in some fifteen or sixteen cases thus treated varied considerably. In many there was a feeling of subjective improvement, without confirmatory objective evidence. In one case of diabetes mellitus a noteworthy reduction in the amount of sugar in the urine took place. In a number of cases of skin disease great relief from itching was afforded. In many if not most of the cases the good results noted, it was thought, could be attributed to the suggestive influence of a new method of treatment. Dr. Theodore LeBoutillier presented a communication entitled "Some Results Obtained by Subcutaneous Injections of Sea-water." He had employed this method of treatment in some seventy-five cases, many occurring in children, and he had observed improvement in the nutrition as a conspicuous result. Dr. H. C. Wood, Jr., read a paper entitled "The Value of Physiological Salt-solution." He pointed out that normal solution is employed as a circulatory stimulant and as a disintoxicating agent. It is especially useful to fill the blood-vessels when the blood pressure is low, for example, after hemorrhage, but it should not be employed when the heart is enfeebled, as it may, under such circumstances, bring about acute dilatation. Dr. S. Louisa Weintraub read a paper entitled "Preliminary Report on the Results of Subcutaneous Injection of Sea-water." She had treated a number of cases of ulcer with brilliant results

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

College of Physicians and Surgeons of Ontario.

May, 1908.

ANATOMY, DESCRIPTIVE.

(All questions of equal value. Any five questions to be answered, but not more than five.)

1. Describe (*a*) the upper extremity, (*b*) the lower extremity, (*c*) ossification of the ulna.
2. Describe the shoulder joint, as to (*a*) articulating surfaces, (*b*) ligaments, (*c*) synovial membranes, (*d*) nerve supply, (*e*) blood supply, (*f*) movements.
3. Name and give origin, insertion, nerve supply, and actions of the muscles of mastication.
4. Describe the lymphatic vessels, and lymphatic glands of the thorax.
5. Describe the prostate gland under the following heads: (*a*) size, (*b*) situation, (*c*) structure, (*d*) blood supply, (*e*) relations.
6. Describe the middle ear.
7. Trace the course; give the relations; name and trace the branches of the posterior tibial artery.
8. (*a*) Describe the sacral plexus and show its method of formation. (*b*) Trace the great sciatic nerve to its termination.
9. Describe (*a*) the fornix, (*b*) corpora quadrigemina, (*c*) opercula insulæ, (*d*) velum interpositum.
10. Describe the capsules, as to (*a*) size, (*b*) situation, (*c*) structure, (*d*) relations, (*e*) blood supply, (*f*) nerve supply.

PHYSIOLOGY AND HISTOLOGY.

1. Give an account of the histological structure of the retina. What portion of the retina is concerned in most acute vision? What is the "blind spot"?
2. Give an account of the histological structure and function of the suprarenal bodies.
3. Describe the development of the lungs. What is meant by the terms residual air and vital capacity?
4. What physical and chemical changes take place in a muscle during contraction?
5. What is the normal arterial blood pressure? Discuss the factors which maintain and alter this pressure.

CHEMISTRY.

(All questions of equal value. The first four questions to be answered, and any two of the remaining four.)

1. Explain fully what is meant, when we say nitrogen is a triad. What is the atomicity of the oxygen and the ozone molecule, and why?
2. One gram of phosphorus is to be converted into the pentachloride, how many litres of chlorine at 15 degrees C. and 780 mm. are required?
3. Compare the physical and chemical properties of sodium and silver, mentioning the group of metals to which each belongs, and why.
4. Define the term paraffin. Give the names of the acids corresponding to the first, second, and third members of the paraffins, and compare their percentage of composition.
5. Define an amine, an amide, and an imide, and mention a member of each group.
6. Give the names and chemical formulæ for bluestone, red precipitate, white vitriol, aqua fortis, mirbane, guncotton, cresol, and urea.
7. To what series of organic acids do each of the following belong: namely, acetic, oxalic, lactic, and tartaric acid? Give the general formula for each series.
8. How would you proceed to estimate the total nitrogen in 10 c.c. of urine by either the Kjeldahl or the Gunning method? Describe the procedure in detail of the method you select, mentioning the apparatus and reagents necessary.

(Atomic Weights.— Chlorine = 35.5; phosporus = 31; sodium = 23; silver = 108; nitrogen = 14; hydrogen = 1; oxygen = 16; carbon = 12.)

MATERIA MEDICA AND PHARMACOLOGY.

(All questions of equal value. Answer any five of the six questions.)

1. Give preparations of, with quantities: (*a*) A normal salt solution. (*b*) A one to two thousand bichloride of mercury solution. (*c*) A 2½% solution of carbolic acid. (*d*) Lime water. (*e*) A nutrient enema.
2. Define with example, styptic, specific, collyrium, alkaloid, alterative.
3. Compare as hypnotics, morphine, chloral hydrate, and sulphonal. Explain antagonism of morphine and atropine.
4. Outline a prescription containing a mineral acid, a nux vomica preparation, and a pepsin preparation.
5. State ordinary or other names for phenol, acetanilidum, nitroglycerinum, hydrargyri subchloridum, pulvis ipecacuanhæ compositus. Give dosage and specific action (shortly) of each.
6. Select a nitrate, a salicylate, a ferrum, an arsenicum, and an iodidum preparation. Give dose and method in detail of prescribing each.

THEORY AND PRACTICE OF MEDICINE.

1. Give the etiology, pathology, and symptoms of tabes dorsalis.
2. Describe a Flint's murmur and the supposed cause of its production. From what other murmur must it be distinguished, and how?
3. Describe chronic uremia, with reference to its occurrence, clinical features and treatment.
4. Give the causes and general symptoms of obstructive jaundice.
5. Give the etiology, clinical history, and physical signs of empyema. Name the chief modes of natural cure.

PATHOLOGY.

1. Discuss the causes and formation of stricture of the urethra. Explain the pathological conditions which may result from it.
2. What are the features which differentiate innocent from malignant growths? Give the gross appearance and microscopic structure of adenoma, or of a glioma.
3. Give the morbid anatomy of bone lesions in hereditary syphilis, and differentiate these from rachitic and tuberculous lesions.
4. Discuss the forms of puerperal infection and the usual modes of entry to the system. Name the lesions which may be produced, and describe briefly the pathology of any one of these lesions.

BACTERIOLOGY.

1. Explain the difference between active and passive immunity. Illustrate by example how each may be acquired.
2. Describe *Bacillus anthracis* under the following heads: morphology, staining, cultural characters, and pathogenicity.

THERAPEUTICS.

1. Give the treatment of a case of acute rheumatic fever.
2. State the therapeutic uses of ergot. Discuss its use in (*a*) hemoptysis, (*b*) hematemesis.
3. Angina pectoris: Give treatment during paroxysm, and in the intervals.
4. Give the treatment of a case of tuberculous peritonitis.

MIDWIFERY, OPERATIVE.

1. The head is lying in the right oblique diameter of pelvis, with the occiput pointing posteriorly: (*a*) Give the position of all the landmarks on making a vaginal examination. (*b*) How may this case end? (*c*) Treat the case if Nature's efforts are not successful.
2. Diagnose a breech. How would you break up a Frank breech?
3. I have diagnosed a case as transverse presentation with the back of the child pointing towards the mother's feet. I am going to perform version: (*a*) What foot will I grasp? Why? (*b*) How would you deliver this after-coming head?
4. Give the symptoms of placenta prævia, and premature separation of the normally implanted placenta. Make a differential diagnosis.

MIDWIFERY, OTHER THAN OPERATIVE, AND PUERPERAL DISEASES.

1. Name the diseases in the mother liable to injure the fetus *in utero*, and enumerate the supposed causes of labor at full time.
2. Give the causes of post partum hemorrhage and the systematic line of treatment to follow.
3. Give the necessary advice to a patient in a case where you suspect eclampsia might supervene.
4. Treat a case of acute infantile colic.
5. What significance would you attach to the discharge of amniotic fluid tinged with meconium: (*a*) Breech presentations; (*b*) vertex presentations.

SURGERY, OPERATIVE.

(All questions of equal value. Any five questions to be answered, but not more than five.)

1. Scirrhus of the mammary gland: Describe minutely the operation necessary for complete removal.
2. For what conditions would you do excision of the elbow? Describe the operation.
3. What symptoms in a movable kidney render operation advisable? Describe one method of operation for same.
4. What conditions require, and what is the usual method of performing (*a*) thoracentesis; (*b*) resection of ribs.
5. Describe the suprapubic and perineal operations for removal of enlarged prostate. Give reasons for your preference in choice of operation.
6. Describe one method of performing colostomy. Give reasons for your choice of operation. State conditions for which the operation may be required.

SURGERY, OTHER THAN OPERATIVE.

(All questions of equal value. Any five questions to be answered, but not more than five.)

1. Define septicemia and pyemia. Distinguish between them; give bacteriology, clinical history, symptoms, diagnosis, and treatment of each.
2. What is tetanus? Give predisposing and exciting causes, clinical history, diagnosis, and treatment.
3. Describe acute infective osteomyelitis. Discuss its clinical history and treatment.
4. What is aneurysm? Describe its structure. Describe popliteal aneurysm, and give its diagnosis and treatment.
5. What are the general principles governing the treatment of fractures at or near joints? Describe Colles' fracture, and give treatment.
6. Describe the clinical history of a case of enlargement of the prostate gland. Describe the general principles of treatment, apart from the operative.

MEDICAL AND SURGICAL ANATOMY.

1. Where would you map out the position of the following structures on the surface of the skull: (*a*) the middle meningeal artery, (*b*) the fissure of Rolando, (*c*) lateral sinus.
2. Where are the reflex centers for the bladder, rectum, ankle clonus, knee jerk, for wrist and elbow jerks?
3. What enters into the formation of the wrist joint?
4. Describe Colles' fracture, Pott's fracture, and deformity in each.
5. What anatomical relations may be determined under normal conditions by a digital examination of the rectum? (*a*) in the male, (*b*) in the female?
6. Give a description of the normal uterus with appendages, as to size and position.
7. Give in some form, the parts cut through in amputation of the leg, upper third, and name of main vessels tied, and where found.
8. What tumors may be found in the right and left inguinal region and in hypogastric regions?
9. Describe Scarpa's triangle, boundaries, and of what importance is it surgically?
10. Give the collateral circulation after ligature of the femoral artery in Hunter's canal.

MEDICAL JURISPRUDENCE.

1. On opening the thorax for a postmortem, what precaution is to be observed?
2. With regard to the external appearance of the heart, what important condition is to be observed?
3. After the removal of the heart, how would you make your incision to examine the interior?
4. Death by suffocation, how is it produced?
5. Give the average weight in an adult of brain, heart, spleen, liver, and kidney.

TOXICOLOGY AND MENTAL DISEASES.

6. Give (*a*) Symptoms of a cocaine poisoning. (*b*) Period when fatal. (*c*) Fatal quantity.
7. What are the special indications of mental weakness.
8. Distinguish between opium poisoning, acute alcoholism, epilepsy, and cerebral hemorrhage.

SANITARY SCIENCE.

1. (*a*) What becomes of the rain that falls during the year? (*b*) What are the objections to using rain water, as it falls, for domestic purposes?
2. (*a*) What are the different sources for water supply? (*b*) Describe three different methods of purifying water for domestic use. (*c*) Name objections to storing water in cisterns. (*d*) How should a cistern be constructed to permit of the safe use of water thus stored?
3. Name the diseases caused by the use of impure water.
4. What do you understand by the term inspection, flushing, and ventilation of sewers?
5. Describe purification and utilization of sewage.
6. Name (only) the methods by which air is vitiated.
7. What are the advantages of a mountain climate, as contrasted with those of the plains?

N. B.—Any of the above questions can be answered in thirty words.

THERAPEUTICS.

1. What are the indications for the use of belladonna (*a*) externally, (*b*) internally? Give the symptoms and treatment of an overdose.
2. Describe fully the treatment for ascites, giving reasons for each measure employed.
3. In a case of deranged heart action, state fully the indications for the employment, respectively, of (*a*) digitalis, (*b*) strophanthus, (*c*) strychnine, (*d*) nitroglycerin.
4. Write prescription for each of the following conditions: (*a*) pleurisy with effusion, (*b*) suppression of urine, (*c*) sciatica, (*d*) alkaline cystitis.

DISEASES OF WOMEN.

1. In making the incision to perform abdominal hysterectomy, you accidentally open the urinary bladder for two inches in extent. Describe in detail your method of repair. What suture material would you use? Would you repair immediately, or at the conclusion of the hysterectomy? What after treatment would be necessary?
2. Give the causes and treatment of pruritus vulvæ.
3. Describe the operation for, and the after-treatment of, repair of complete perineal rupture—say eight months after confinement.
4. A mass the size of a small orange is found in the posterior *cul-de-sac;* differentiate between retrodisplaced uterus, fibroid of the uterus, and ovarian cyst.
5. In using the uterine sound give the: (*a*) preliminary preparation, (*b*) indications, (*c*) contraindications, and (*d*) dangers.

DISEASES OF CHILDREN.

1. Define laryngismus stridulus (spasmodic croup), and give the predisposing and exciting causes, symptoms, the diseases for which it may be mistaken, and its treatment.
2. Discuss briefly the diagnostic values of Kernig's and Babinski's reflexes. What change, if any, occurs in the patellar reflex (knee jerk) in lobar pneumonia?
3. Diagnose and treat a case of acute rheumatic endocarditis in a child ten years old.
4. Acute osteomyelitis: (*a*) Name in order the three most common infecting germs, (*b*) the three bones in which it most frequently occurs, (*c*) and the diseases for which it may be mistaken. What would be your treatment of an acute attack of the *very early* stage of the disease, as soon as you felt fairly sure of your diagnosis?
5. A child 4 years old receives a penetrating wound of the brain from the tine of a pitchfork. The point of entry is one inch above the meatus auditorius externus, and the fork goes straight in, horizontally, to a depth of three inches or half-way through the brain. Name in some order the structures that would be pierced. What symptoms would likely follow and the treatment from the beginning to the end of the case.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

College of Physicians and Surgeons of Ontario.

May, 1908.

PHYSIOLOGY AND HISTOLOGY.

1. The *retina* is composed of several layers, from without inwards, as follows: (1) layer of pigment cells; (2) layer of rods and cones; (3) the external limiting membrane; (4) the outer nuclear, or granular, layer; (5) the outer molecular, or reticular, layer; (6) the inner nuclear, or granular, layer; (7) the inner molecular, or reticular, layer; (8) the layer of ganglion cells; (9) the layer of nerve fibers; and (10) the internal limiting membrane.

These structures are bound together by sustentacular fibers or neuroglia.

The portion concerned in most acute vision is the macula lutea, and especially its central portion, the fovea.

The *blind spot* is that part of the retina at which the optic nerve enters; it is occupied entirely by fibers of the optic nerve, and is devoid of any elements of the retina; it is insensitive to light.

2. The *function of the suprarenal bodies* is not defi-

nitely settled; they produce an internal secretion which is probably necessary to life, which is also said to increase the blood pressure by a vasomotor action on the arterioles; some tonic action on the cardiac muscle is also attributed to them; and it is supposed that they are able to destroy or remove some toxic substances.

3. *Residual air* is the air which still remains in the lungs after the deepest expirations. It measures about 100 cubic inches.

Vital capacity is the amount of air which can be expelled from the lungs by an extraordinary expiration after the most forcible inspiration. It includes the tidal, complemental, and reserve air, and measures about 225 to 230 cubic inches.

4. During contraction the following changes take place in a muscle:

(1) It becomes shorter and thicker, but the volume remains the same.
(2) It consumes oxygen.
(3) It sets free carbon dioxide.
(4) It forms sarcolactic acid.
(5) It becomes acid in reaction.
(6) It becomes more extensible and less elastic.
(7) There is an increase in heat production, and consequently a rise of temperature.
(8) The electrical reaction becomes relatively negative.

5. The normal arterial blood pressure varies; the systolic pressure being about 120 to 150 mm. of mercury, and the diastolic from about 90 to 120 mm. of mercury.

Blood pressure is *maintained* by the contraction of the heart, the peripheral resistance, and the elasticity of the arterial walls.

Blood pressure:

May be raised—	May be lowered—
1. By the heart beating more quickly.	1. By the heart beating more slowly.
2. By the heart beating more powerfully.	2. By the heart beating more feebly.
3. By contraction of the arterioles.	3. By dilatation of the arterioles.
	4. By deficient supply of blood to the left ventricle.

CHEMISTRY.

1. The combining power of one atom of nitrogen is equal to three times that of an atom of hydrogen; or one atom of nitrogen can combine with or replace three atoms of hydrogen (or other univalent element).

The atomicity of the oxygen molecule is two, because one molecule of oxygen (O_2) contains two atoms.

The atomicity of the ozone molecule is three, because one molecule of ozone (O_3) contains three atoms.

2. The equation is $P_4 + 10\,Cl_2 = 4\,P\,Cl_5$.

(4×31) grams P require (10×22.4) liters Cl.

124 grams P require 224 liters Cl, at normal temperature and pressure.

$\therefore$ 1 gram P requires $\frac{224}{124}$ liters Cl, at normal T and P, but at 15° C. and 780 mm. pressure:

1 gram P will require $\left(\frac{224}{124} \times \frac{273+15}{273} \times \frac{760}{780}\right)$ liters Cl.

$= \frac{224}{124} \times \frac{288}{273} \times \frac{760}{780} = \frac{68096}{36673} = 1.85$ .. LITERS OF CHLORINE.

3. *Sodium* is a silver-white metal, is waxy at ordinary temperature, becomes quickly tarnished, and coated with a yellow film in air. It oxidizes in air; it burns with a yellow flame; it decomposes water with evolution of hydrogen. It is univalent, and has atomic weight of 23.

Silver is a white metal, soft, malleable, and ductile; is not acted on by pure air, but is blackened in air containing H_2S. It makes an alloy with many metals. It is an excellent conductor of heat and electricity. It is univalent, and has atomic weight of 107.

Sodium belongs to the group of alkali metals (Li., Na., K., Ce.); because the properties of these elements are similar.

Silver resembles the members of the same group in *chemical* properties, and therefore might be placed with them; but its *physical* properties are more like those of copper, or gold, or mercury, and it has been classed by various writers with each of these metals.

4. *Paraffin* is a name given to the members of the methane series of organic compounds. They are saturated hydrocarbons, and have the general algebraic formula $C_n H_{2n+2}$.

ACIDS IN THIS SERIES.	FORMULA.	PERCENTAGE COMPOSITION.		
		C	H	O
1. Formic acid.	H. COOH.	26.08	4.34	69.56
2. Acetic acid.	CH_3. COOH.	40.00	6.66	53.33
3. Propionic acid.	CH_3. CH_2. COOH.	48.64	8.11	43.23

5. An *amine* is a substance derivable from ammonia by the substitution of a hydrocarbon radical for part or all of the hydrogen.

Example:—

Ammonia.

Methylamine.

An *amide* is a substance derivable from ammonia by the substitution of an oxidized radical for part or all of the hydrogen.

Example:—

Ammonia.

Acetamide.

An *imide* is a compound derived from a dicarboxylic acid by the substitution of NH for 2 OH.

Example:—

Oxalic acid.

Oximide.

6.

	NAME.	CHEMICAL FORMULA
Bluestone.	Cupric sulphate.	$CuSO_4$
Red precipitate.	Mercuric oxide.	HgO
White vitriol.	Zinc sulphate.	$ZnSO_4$
Aqua fortis.	Nitric acid.	HNO_3
Mirbane.	Nitrobenzene.	$C_6H_5NO_2$
Guncotton.	Hexanitrocellulose	$C_{12}H_{14}(ONO_2)_6O_4$
Cresol.	Methyl phenol.	$C_6H_4OH.CH_3$
Urea.	Carbamide.	CON_2H_4

7.

ACID.	SERIES, WITH GENERAL FORMULA OF SERIES.	
Acetic.	Paraffin monocarboxylic acids.	$C_nH_{2n}O_2$
Oxalic.	Paraffin dicarboxylic acids.	$C_nH_{2n-2}O_4$
Lactic.	Oxyacetic acids.	$C_nH_{2n}O_3$
Tartaric.	Dioxydicarboxylic acids.	$C_nH_{2n-2}O_6$

8. "For the *determination of total nitrogen* 5 c.c. of urine are placed in a long-necked Kjeldahl digesting flask along with 0.5 gm. of $CuSO_4$ and 15 c.c. of concentrated H_2SO_4. The flask is supported at 45° to the horizontal and gradually heated until white fumes are given off; 10 gm. of K_2SO_4 are then added, and the contents of the flask heated just short of boiling until almost colorless. After cooling, the contents of the digesting flask are transferred and washed into a distilling flask; the acid is nearly neutralized by the slow addition of NaHO solution (sp. gr. 1.24); a few pieces of granulated zinc are added, and then a moderate excess of NaHO solution, whereupon the flask is immediately connected with a bulb tube and condenser, so arranged as to deliver the distillate into a recipient containing 30 c.c. of N/5 H_2SO_4 and a little lacmoid as an indicator. The distillation is continued until about two-thirds of the liquid have passed over, when the excess of H_2SO_4 remaining in the recipient is determined by titration with N/5 NaHO solution. Each c.c. of N/5 acid neutralized by the ammonia formed in the process corresponds to 0.0028 gm. of nitrogen in the 5 c.c. of urine used. A blank process must be conducted with reagents alone to guard against error from nitrogen compounds in the reagents or in the air." (Witthaus's *Manual of Chemistry*.)

To estimate the amount of nitrogen in 10 c.c. of urine, multiply this result by two.

MATERIA MEDICA AND PHARMACOLOGY.

1. (*a*) A *normal salt solution* can be made by adding 1½ drams of sodium chloride to one quart of sterile water.

(*b*) A *one to two thousand bichloride of mercury solu-*

tion can be made by adding 7½ grains of mercury bichloride to a liter of water.

(*c*) *A 2½ per cent. solution of carbolic acid* can be made by adding 6 drams of carbolic acid to a liter of water.

(*d*) *Lime water* is a saturated solution of lime. It is made by washing slaked lime and shaking it up in distilled water, using about one grain of lime to each ounce of water. After it settles the water is poured off from the sediment and strained.

(*e*) *A nutrient enema* can be made with 8 ounces of milk, three eggs, and half a dram of salt.

2. *Styptic* is an agent which, on being applied locally, stops bleeding. *Example*:—Silver nitrate.

Specific is an agent which has a distinctly curative effect on a particular disease. *Example*:—Quinine, in malaria.

Collyrium is an eye wash. *Example*:—Boric acid in distilled water (gr. j, or ij to ℥j).

Alkaloid is a basic nitrogenous substance of alkaline reaction, and capable of combining with acids to form salts in the same way that ammonia does. *Example*:—Morphine.

Alterative is an agent which modifies the course of a disease for the better; its action is not determined, but probably it promotes waste and favorably modifies nutrition. *Example*:—Arsenic.

3. *Morphine* is the best where pain is present; it acts quickly, but it is most apt to cause a habit formation, and therefore should not be used unless necessary.

Chloral hydrate produces a natural sleep, acts promptly, but is of no service if pain is present; it also lowers the body temperature. It can be given for a long time without deleterious effect, but it may irritate the tissues and weaken the heart.

Sulphonal produces a natural sleep, but is of slow action, requiring 3 or 4 hours to take effect; it is of no use if pain is present, does not irritate the tissues and weaken the heart, but is probably not so good for continuous use as chloral hydrate, though the two may replace each other for a time.

"The *antagonism* between *morphine* and *atropine* is in part real, such as their respective effects on the convolutions, respiratory center and intestines. In part it is apparent only. Thus, the contraction of the pupil caused by morphine occurs through the pupillary center; the dilatation caused by atropine is referable to paralysis of the ciliary branches of the third nerve. Morphine is diaphoretic through the centers; atropine is anhydrotic through the terminal nerves of the glands. Both depress the heart and reduce blood pressure in poisonous doses. Thus morphine and atropine are not true antagonists, but the one may prevent or relieve certain effects of the other, and may therefore be (1) combined with the other for particular medicinal purposes, or (2) given in the treatment of poisoning by the other under particular circumstances." (J. Mitchell Bruce, *Materia Medica and Therapeutics.*)

4. Glycerini pepsini ℥j.
Tincture nucis vomicæ.
Acidi hydrochlorici diluti ää ♏xl.
Aquæ destillatæ q.s. ad ℥iv. Misce.
Signa:—One tablespoonful three times a day.

5.

	ORDINARY, OR OTHER NAME.	DOSE.
Phenol.	Carbolic acid.	1 to 3 grains.
Acetanilidum.	Antifebrin.	1 to 3 grains.
Nitroglycerinum.	Glonoin.	1 drop of a 1% solution.
Hydrargyri subchloridum.	Calomel.	½ to 5 grains.
Pulvis ipecacuanhæ compositus.	Dover's powder.	5 to 15 grains.

THEORY AND PRACTICE OF MEDICINE.

2. *Flint's murmur* is a presystolic murmur heard at the apex of the heart in some cases of aortic regurgitation. It is *supposed* to be due to the vibration of the anterior cusp of the mitral valve, as it lies between the regurgitating blood stream and that which is flowing into the left ventricle from the left auricle.

It is to be distinguished from mitral stenosis. This is best done by a study of the pulse, which is very different in these two conditions.

PATHOLOGY.

2. *Benign tumors* are encapsulated, do not tend to infiltrate the surrounding tissues, do not give rise to metastatic growths, do not tend to recur after removal, do not produce cachexia, and do not have a fatal tendency (except from their location).

Malignant tumors are not encapsulated, tend to infiltrate the surrounding tissues, give rise to metastatic growths, have a tendency to recur after removal, give a cachexia, have a fatal tendency.

Glioma is usually single, but may be multiple, is soft, gelatinous, grayish or pink, according to the number of blood-vessels in it, the outline is not distinct. Microscopically, it contains glia cells, with a small amount of protoplasm, but large, round or oval nuclei, and many thin fibrils which interlace with each other.

BACTERIOLOGY.

1. "*Active immunity* follows an attack of a certain disease and secures immunity for that alone, which may last but a short time (erysipelas, cholera) or for a longer period (typhoid), or even for life (variola); or it follows inoculation of a virus weaker than necessary to cause the typical disease (vaccination against smallpox); or it follows inoculation by bacterial products apart from the organisms themselves.

"*Passive immunity* is the term applied to the effect of a serum derived from an immunized animal and injected into one not immune, the theory being that in the blood of the former there is a chemical substance (antitoxin) which neutralizes the toxin in the donating animal, or otherwise it would show symptoms, and by borrowing its serum for the infected animal the toxin is opposed by the alien antitoxin."—(From Thayer's *Pathology.*)

2. BACILLUS ANTHRACIS. *Morphology:* It is a large, rod-shaped microorganism, with slightly thickened ends; it is from 5 to 20 mikrons in length, and a little more than one mikron in breadth; it has a tendency to form long threads; it is nonmotile and nonflagellated; it is aërobic.

Staining:—It stains by all the alkaline aniline dyes, and also by Gram's method.

Cultural characters:—It grows on practically all media, as a film on potato, in tree form in gelatin stab, it liquefies gelatin and also serum.

Pathogenicity:—It causes anthrax, splenic fever, malignant pustule, and woolsorter's disease. Infection takes place through wounds, or by the respiratory or alimentary tract. The bacilli are probably destroyed by the gastric juices, but not so the spores.

MIDWIFERY, OPERATIVE.

1. (a) The occiput is depressed and posterior, and points to the right sacroiliac synchondrosis; the smaller fontanelle is in the same locality. The sagittal suture runs obliquely forward and to the left, in the line of the right oblique pelvic diameter. The shoulders lie at right angles to this, in the left oblique pelvic diameter. The anterior fontanelle may be felt anteriorly, high up and to the left.

(*b*) The case may end: (1) By anterior rotation of the occiput, (2) the occiput may remain posteriorly in the hollow of the sacrum; (3) a face presentation may result; (4) the labor may become arrested, or uterine inertia may ensue.

(*c*) (1) Manual rotation and extraction by forceps may be tried; or (2) forceps, rotation, and extraction; or (3) forceps extraction, with the occiput remaining posterior.

4. The differential points between placenta prævia and premature separation of a normally attached placenta are shown in the following table (from Dorland's *Obstetrics*):

PLACENTA PRÆVIA.	PREMATURE DETACHMENT.
Most commonly manifests itself after the sixth month of gestation, but may occur as early as the second month.	Most commonly occurs during the first stage of labor, but may occur at any time during the last three months of pregnancy.
The hemorrhage is abrupt, but painless.	The hemorrhage is sudden, and generally is attended with sharp pain.
There are generally repeated hemorrhages of increasing severity.	Hemorrhage persists until the uterine contents are evacuated or the patient perishes.
There is an edematous condition of the cervix and lower uterine segment, with marked pulsation.	Vaginal examination reveals no deviation from the condition normal to pregnancy.
Cervix is generally quite patulous, and within may be detected the placenta.	The cervix is perhaps (if labor be initiated) slightly patulous.
The placental bruit is situated low down.	The placental bruit is in normal position.

MIDWIFERY OTHER THAN OPERATIVE, AND PUERPERAL DISEASES.

1. The diseases of the mother liable to injure the fetus *in utero* are: Malaria, relapsing fever, typhoid, typhus, yellow fever, scarlet fever, measles, smallpox, cholera, pneumonia, cardiac disease with inadequate compensation, exophthalmic goiter, hepatic disease and jaundice, toxemia, eclampsia, diabetes, and pernicious anemia.

The *causes of labor at full term* are not definitely known. Among the theories held, or factors supposed to be involved, are the following: (1) The gradual distention of the uterus at the end of pregnancy, after it has reached the physiological limit of its growth, while the contents still continue to grow; (2) the fetus becomes a "foreign body," and as such excites uterine contractions and is extruded; (3) fatty degeneration of the placenta and of the decidua; (4) the circulation of toxic products in the placental blood acts upon a center in the medulla and so produces labor.

5. (*a*) In a *breech* presentaation the discharge of meconium has no significance. (*b*) In a *vertex* presentation it is a danger signal, and implies a compressed cord, or fetal apoplexy, and delivery should be hastened.

SURGERY, OPERATIVE.

2. *Excision of the elbow* is performed for: Chronic joint disease (generally tuberculosis); wounds; faulty ankylosis, or other deformity; disease of the articular ends of the bones; fracture dislocation; compound comminuted fracture.

MEDICAL AND SURGICAL ANATOMY.

1. (*a*) The *middle meningeal artery* crosses the anterior inferior angle of the parietal bone at a point 1½ inches behind the external angular process of the frontal bone, and the same distance above the zygoma. From this point the anterior branch passes upward and somewhat backward toward the sagittal suture, lying a little over half an inch behind the coronal suture. The posterior branch passes upward and backward over the squamous portion of the temporal bone.

(*b*) To *locate the fissure of Rolando on the scalp*: Draw a straight line over the top of the scalp from the inion to the glabella; bisect this line, and half an inch posterior to the midpoint draw a line downward and forward at an angle of 67.5° for a distance of 3½ inches. This line will represent the location of the *fissure of Rolando*.

(*c*) The course of the *lateral sinus* is represented by a line drawn from the external occipital protuberance to the base of the mastoid process, and another line from the base of the mastoid to its tip.

2. The *reflex center* for the *bladder*, in the lumbar enlargement of the spinal cord; for the *rectum*, in the lumbar enlargement of the spinal cord; for *ankleclonus*, in the anterior horns of the third to fifth sacral segment of the spinal cord; for *knee jerk*, in the anterior horns of the second to fourth lumbar segments of the spinal cord; for *wrist jerk*, in the anterior horns of the sixth to eighth cervical segment of the spinal cord; for *elbow jerk*, in the anterior horns of the sixth cervical segment of the spinal cord.

3. The *parts entering into the formation of the wrist joints are:* The lower end of the radius, the under surface of the interarticular fibrocartilage, and the scaphoid semilunar and cuneiform bones; cartilage, anterior, posterior, external lateral, and internal lateral ligaments, and synovial membrane.

4. *Colles's fracture* is a fracture of the lower end of the radius; it is generally transverse, and is usually within an inch or an inch and a half of the articular surface. There is a characteristic deformity caused by the lower fragment, and the carpus forming a prominence on the dorsal surface; at the same time there is a projection on the palmar surface just above the wrist, caused by the upper fragment. The hand is abducted and pronated, and the styloid process of the ulna becomes very prominent.

Pott's fracture consists of a fracture of the lower end of the fibula, about three inches above the tip of the malleolus; and a fracture of the internal malleolus. The foot is twisted outward, the sole everted, and the heel drawn up; there is a depression at the site of the fracture, the inner malleolus either projects prominently or the fragment can be felt and crepitus elicited; the foot is shortened and the ankle is swollen and widened.

5. By a digital examination of the rectum there can be made out: The external sphincter, the internal sphincter, the rectal insertion of the levatores ani, the anal canal, the condition of the ischiorectal fossæ, the coccyx, hollow of sacrum, lower part of sacrum, tuberosity of ischium, wall of pelvis, great sacrosciatic ligament. In addition, in the *male*: The membranous urethra, the prostate, vasa deferentia, seminal vesicles, distended bladder. In the *female*: Perineal body, rectovaginal septum, os uteri, cervix uteri, ovaries.

7. The parts cut through in amputation at the upper third of the leg are: Skin; fascia; bones, tibia, and fibula; interosseous membrane; muscles, tibialis anticus, tibialis posticus, extensor longus digitorum, extensor proprius hallucis, flexor longus hallucis, flexor longus digitorum, peroneus longus, peroneus brevis, soleus, gastrocnemius, and the tendon of the plantaris; arteries, anterior tibial, posterior tibial, peroneal; veins, the venæ comites of the arteries, external saphenous, internal saphenous; nerves, anterior tibial, posterior tibial, external saphenous, communicans peronei, musculocutaneous.

The main vessels tied are: The anterior tibial, in front of the interosseous membrane; the posterior tibial, beneath the deep transverse fascia and behind the tibia; the peroneal, beneath the deep transverse fascia and behind the fibula.

8. In the *right inguinal* region may be found: Ovarian tumors, pelvic abscesses, diseases of the cecum and appendix, fecal impaction, hernia.

In the *left inguinal* region may be found: Tumor of the sigmoid, ovarian tumors, pelvic abscesses, volvulus, fecal impaction, hernia.

In the *hypogastric* region may be found: Distended bladder, uterine tumors and cysts, pregnant uterus.

9. *Scarpa's triangle* is a triangular area or depression situated just below the fold of the groin. It is bounded *above* by Poupart's ligament, *externally* by the Sartorius, and *internally* by the inner margin of the Adductor longus; its *apex* is formed by the junction of the Adductor longus and Sartorius. The *floor* is formed, from without inward, by the Iliacus, Psoas, Pectineus, Adductor brevis, and Adductor longus. *Contents*: The femoral vessels pass from about the center of the base to the apex, the artery being on the outer side of the vein; the artery gives off the superficial and profunda branches, and the vein receives the deep femoral and internal saphenous; the anterior crural nerve lies to the outer side of the femoral artery; the external cutaneous nerve is still further external, lying in the outer corner of the space; just to the outer side of the femoral artery, and in the sheath with it, is the crural branch of the genitocrural nerve. At the apex, the vein (which at the base was internal to the artery) lies behind the artery. The triangle also contains fat and lymphatics. Its *surgical importance* is due to the number of important structures which it contains (see above). Its apex is the point for ligating the femoral artery; digital pressure, or ligation, is applied here in case of popliteal aneurysm; femoral hernia appears in the upper part, and psoas abscess often points here, too.

10. The collateral circulation after ligature of the femoral artery in Hunter's canal: (1) The external circumflex; with the lower muscular branches of the femoral, anastomotica magna, superior articular of the popliteal, and anterior tibial recurrent. (2) The perforating and terminating branches of the profunda; with muscular branches of the femoral, and muscular and superior articular branches of the popliteal. (3) The comes nervi ischiadici; with the perforating branches of the profunda, and the articular branch of the popliteal.

MEDICAL JURISPRUDENCE.

4. Death by suffocation is due to asphyxia; that is, air cannot get to the blood, and eventually the respiratory center becomes paralyzed by the prolonged action of the increasingly venous blood.

5. The average weight in an adult of the *brain* is: male, 49½ ounces; female, 44 ounces. *Heart*, male, 10 to 12 ounces; female, 8 to 10 ounces. *Spleen*, about 7 ounces. *Liver*, male, 50 to 60 ounces; female, 40 to 50 ounces. *Kidney*, male, 4½ to 6 ounces; female, 4 to 5½ ounces.

TOXICOLOGY AND MENTAL DISEASES.

1. Cocaine Poisoning. (*a*) *Symptoms:* "When a large dose has been taken the symptoms are not unlike those of atropine poisoning. There is dryness of the throat, tongue, and nose, difficulty of swallowing, faintness, and sometimes nausea and vomiting. The pulse is usually increased in fullness and frequency at first. The respiration also becomes more rapid, and there is much general nervous excitement, with general hyperesthesia. The eyes are bright and staring and the pupils dilated. The patient talks volubly and incoherently. Sometimes an erythematous eruption appears on the skin. The stage of depression soon comes on, when the breathing becomes shallow, the heart's action more rapid, and the face pale or cyanotic. The surface becomes anesthetic, and muscular twitchings

and paralysis precede death, which is generally caused by paralysis of respiration."

(*b*) *Period when fatal:*—Less than one hour. If the patient survive half an hour the prognosis is good.

(*c*) *Fatal quantity:*—15½ grains. The smallest fatal dose on record is 1.2 grain for an adult. Twelve drops of a 4 per cent. solution hypodermically caused the death of a girl eleven years of age in 40 seconds. Twenty-two grains by the mouth and 10 grains hypodermically have been recovered from.—(Riley's *Toxicology.*)

2. The *special indications of mental weakness* are: Lack of attention, inability to concentrate the mind on one's work, loss of memory, incoherence, personal untidiness and neglect, hallucinations and illusions, lack of decision and will power, irritability of temper and disposition, insomnia.

3. In *opium poisoning* the pupils are contracted, respiration is slow, pulse slow and full, body temperature is normal or subnormal, there may be the odor of laudanum on the breath.

In *acute alcoholism* the patient can generally be aroused; the coma is not, as a rule, complete; the face may be flushed; the pupils are normal or dilated; the respirations are normal in frequency, but deep; the skin is cool and moist, and the body temperature may be below normal; there may be the odor of alcohol on the breath.

In *epilepsy* there will be a brief aura, sudden and complete loss of consciousness, pupils dilated and rigid, the tongue will be bitten (unless prevented), the sphincters may be relaxed, there may be a slight rise of temperature.

In *cerebral hemorrhage*:—There are generally paralysis of the head and upper limbs; and in left-sided lesions there may be aphasia; the pulse is slow and full; the respirations are at first slow, regular, and stertorous, later on becoming of the Cheyne-Stokes type.

SANITARY SCIENCE.

1. (*a*) Of the rain that falls:—Part is evaporated; part flows off in streams and rivers; part sinks into the earth through cracks and fissures and flows toward some water channel or the sea; and part comes back to the surface again in the form of springs.

(*b*) The objections to using rain water as it falls are:—The rain takes up gases from the air (chiefly oxygen, nitrogen, and carbon dioxide), but also ammonia, nitrous and nitric acids; also suspended matters which may be floating in the air, such as soot. In this way impurities may be present to the extent of 2½ grains per gallon of water.

2. (*a*) The sources of water supply are: Rain and snow; (2) surface waters (rivers, lakes, and ponds); (3) subsoil or ground water; (4) deep waters (spring and artesian well).

(*b*) Three methods of purifying water:—Distillation, filtration, and boiling.

3. Diseases caused by the use of impure water are:—Typhoid, cholera, dysentery, diarrhea, goitre, intestinal parasites, metallic poisoning, vesical calculi.

6. Air is vitiated by:—The respiration of men and animals; the products of combustion and artificial lighting; substances yielded by factories, workshops, mines, sewers, marshes, cemeteries, etc.; organic products given off by human beings.

7. The advantages of a mountain climate, as contrasted with plains, are:—(1) Greater movement of air, strong winds; (2) less humidity; (3) more sunlight; (4) less suspended mattter in the air; (5) a lower temperature.

DISEASES OF WOMEN.

2. Pruritus vulvæ may be *caused by:* Parasites; diseases of the vulva, as inflammation, edema, vegetations, congestion; irritating discharges; lack of cleanliness; diabetic urine; it may also be of nervous origin, or idiopathic.

Treatment consists in removing the cause, if possible; cleanliness, fresh air, tonics, and general attention to hygiene; local applications of solution of bichloride of mercury, 1 : 2,000; or carbolic acid, 1 : 100; or lead and opium; dusting powders of bismuth subnitrate, calomel, or zinc oxide are also useful.

5. (*a*) Preliminary preparation includes all the usual antiseptic and aseptic precautions.

(*b*) The *uses* of the uterine sound are:—(1) To demonstrate the mobility of the uterus; (2) to show the size of the uterus; (3) the presence of intrauterine growths; (4) deviations in the cervical canal, and (5) as an aid in the diagnosis of uterine displacements.

(*c*) *Contraindications*:—(1) The least suspicion of even the possibility of pregnancy; (2) menstruation; (3) acute endometritis; (4) malignant disease of the uterus or vagina; (5) acute pelvic inflammation.

(*d*) *Dangers*:—(1) Abortion; (2) sepsis; (3) peritonitis; (4) hemorrhage; (5) perforation of the uterus.

DISEASES OF CHILDREN.

2. *Kernig's reflex* (or sign) is present in meningitis or cerebrospinal fever in nearly every case. It is very rarely present in other conditions, hence it is a sign of much value.

Babinski's reflex is said to indicate disease of the pyramidal tract, except in children under two years of age, when the reflex is normal. Its absence does not prove that the pyramidal tracts are not diseased. There is still much uncertainty as to the value of this reflex, its chief value being in differentiating organic disease of the lateral columns from so-called "functional" conditions.

In *lobar pneumonia*, if the toxic condition is very severe, the patellar reflex may be exaggerated.

4. *Acute osteomyelitis.* (*a*) The three most common infecting germs are: *Staphylococcus pyogenes aureus, Staphylococcus pyogenes albus,* and *Streptococcus pyogenes.*

(*b*) The three bones most frequently affected: Femur, tibia, and humerus (or radius).

(*c*) Diseases for which it may be mistaken: Rheumatism, gonorrheal rheumatism, typhoid fever, tuberculous arthritis, cellulitis, and infantile scurvy.

Treatment is immediate incision down through the periosteum; the surface of the bone must be opened with gouge or chisel, pus evacuated, and drainage instituted; irrigation with hot bichloride solution and packing with gauze. The medulla of the bone must be freely exposed, and any suppurating material removed. Constitutional treatment and rest, are, of course, indicated.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION
Alabama*	W. H. Sanders, Montgomery	Montgomery, July 13
Arizona*	Ancil Martin, Phoenix	Phoenix, July 5
Arkansas*	F. T. Murphy, Brinkley	Little Rock, April 13
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco, Aug. 3
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver, July 6
Connecticut*	Chas. A. Tuttle, New Haven	New Haven, July 13
Delaware	J. H. Wilson, Dover	Dover, June 15
Dist. of Col'bia.	Geo. C. Ober, Washington	Washington, April 13
Florida*	J. D. Fernandez Jacksonville	Tallahassee, May 19
Georgia	E. R. Anthony, Griffin	Atlanta, April 30
Idaho*	W. B. Howard, Pocatello	Boise, Oct. —
Illinois	J. A. Egan, Springfield	Chicago, April 15
Indiana	W. T. Gott, Crawfordsville	Indianapolis, May 2
Iowa	Louis A. Thomas, Des Moines	Des Moines, 8
Kansas	D. P. Cook, Clay Center	Kansas City, June
Kentucky	J. N. McCormick, Bowling Green	Louisville, April 27
Louisiana	F. A. LaRose, 211 Camp Street, New Orleans	New Orleans, May 20
Maine	Wm. J. Maybury, Saco	Augusta, July 1
Maryland	J. McP. Scott, Hagerstown	Baltimore, June 15
Massachusetts*	E. B. Harvey, State House, Boston	Boston, May 11
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor, June 8
Minnesota	W. S. Pillerton, St. Paul	St Paul, June 1
Mississippi*	S. H. McLean, Jackson	Jackson, May 11
Missouri	J. A. B. Adcock, Warrensburg	Kansas City, May 4
Montana*	Wm. C. Riddell, Helena	Helena, Oct. 5
Nebraska	E. J. C. Sward, Oakland	Lincoln, May —
Nevada	S. L. Lee, Carson City	Carson City, May 3
N. Hampshire	Henry C. Morrison, State Library, Concord	Concord, June 29
New Jersey	J. W. Bennett, Long Branch	Trenton, June 15
New Mexico	J. A. Massie, Santa Fe	Santa Fe, April 12
New York	C. F. Wheelock, Univ. of State of New York, Albany	New York, Albany, Syracuse, Buffalo, May 18
N. Carolina	B. K. Hays, Oxford	Asheville, June 9
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks, July 6
Ohio	Geo. H. Matson, Columbus	Columbus, June 8
Oklahoma*	F. P. Davis, Enid	Guthrie, April 13
Oregon*	B. E. Miller, Portland	Portland, July 6
Pennsylvania*	N. C. Schaeffer, Harrisburg	Philadelphia, Pittsburg, June 22
Rhode Island*	G. T. Swarts, Providence	Providence, July 1
S. Carolina	H. H. Wyman, Aiken	Columbia, June 8
S. Dakota*	H. E. McNutt, Aberdeen	Watertown, July 14

FREEZING AS A THERAPEUTIC MEASURE; LIQUID AIR AND CARBONIC ACID SNOW.*

BY GEORGE T. JACKSON, M.D.,

NEW YORK.

PROFESSOR OF DERMATOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY,

AND

S. DANA HUBBARD, M.D.,

NEW YORK.

CLINICAL ASSISTANT, DERMATOLOGICAL DEPARTMENT, VANDERBILT CLINIC.

"SOME are born great, some achieve greatness, and some have greatness thrust upon them:" and some, alas! do not receive the credit that is their due. The latter fate threatens to befall the late Dr. A.

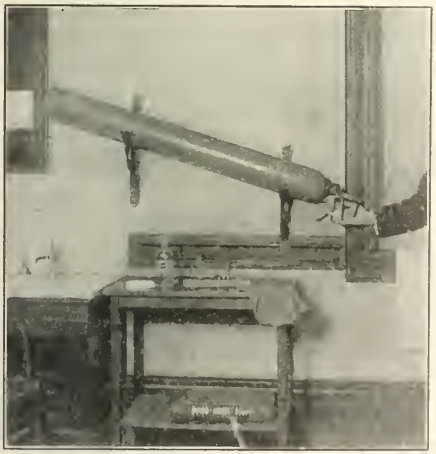

FIG. 1.—Liquid carbonic apparatus. The drum is shown on the wall brackets; socket wrench on distal end of valve; chamois chamber for making snow, previous to closing; on the table are molds for compressing and shaping the snow, also the ether bottle and cup to hold the ether for dipping before application.

Campbell White who was the first to use liquid air as a therapeutic measure. In 1899 he published in the MEDICAL RECORD the first report of his work We who use liquid air are but followers of Dr. White, and to him should be given all the honor that is due to a discoverer. And yet his name is seldom found in the literature of the subject.

Many of the early experiments of Dr. White were made at the Vanderbilt Clinic, in the Dermatological Department, through the courtesy of Professor George Henry Fox, of the College of Physicians and Surgeons. From these, we, of the clinic, learned how to use liquid air, and have continued to use it until recently, when, on account of a stoppage in the supply, we began the use of carbonic acid snow as a substitute.

In 1905 Dr. C. T. Dade, one of the clinical assistants of the Dermatological Department of the Vanderbilt Clinic, who had taken special interest in the use of the air, was invited to give a demonstration of it before the American Dermatological Association then meeting in New York. This suggested to Dr. W. A. Pusey of Chicago, who was present, the possibilities of liquid carbonic acid gas as a substitute for liquid air. To him is due the credit of devising the method of using this agent in the form of snow. Shortly after the above-mentioned meeting we heard of Dr. Pusey's experiments with carbonic acid gas and obtained a drum of it for the clinic. Our early attempts at using it were not successful. It was not until September, 1907, when Dr. Pusey was in this city to attend the meeting of the Sixth International Dermatological Congress that we learned how to make the snow. He very courteously went with one of us (Dr. Hubbard) to the office of the manufacturer of the gas, and showed his method of working. Since then the same one of us has further developed the technique, as will be described later.

By one of those curious coincidences so often occurring, at about the time the use of liquid air suggested to Dr. Pusey the substitution of liquid carbonic acid gas for it, that is in 1905, the attempts to use ethyl chloride as a freezing agent for certain diseases of the skin suggested to Dr. M. Juliusberg, in Germany, the use of liquid carbonic acid gas as a substitute for it. He employed it in the form of a spray with a special apparatus, and reported some successful results.

FIG. 2.—Snow chamber filled with solidified carbonic acid.

Liquid Air was first made in appreciable amount by Dewar in England about 1877. Since then several machines for making it have been devised. The liquid air used by Dr. White was supplied by

*Read before the Medical Society of the County of New York, March 22, 1909.

Charles E. Trippler of this city and made by a machine invented by him. In his machine the atmospheric air is dried and cleared from impurities by chemical filtration, and then forced by means of a horizontal double-acting pump into a tank under a pressure of 100 pounds to the square inch. From

Fig. 3.—Application of the carbonic snow to the lesion in a case of lupus erythematosus; the operator is timing the application, watch in hand.

tank No. 1 it is drawn by a second horizontal pump of similar capacity and forced into a second tank under a pressure of 800 pounds to the square inch, passing on its way through coiled copper tubing jacketed with water in circulation to cool the pipes and remove the heat from the air. In this tank it

Fig. 4.—A case of lupus vulgaris on the ear, showing the glistening fluid exuding from a recently formed blister following the application of carbonic snow.

remains until cooled thoroughly. Then a third pump forces the air through another coil of copper tubing jacketed with water flowing in a direction opposite to the flow of air, into tank No. 3, under a pressure of 2,000 pounds to the inch. From this tank it goes into a container. This is a thin, strong metal box set in wool packing. In the upper two-thirds of the container there are coils of tubing jacketed with water. When the air is shown by the gauge to be under proper pressure, and by the thermometer to be of proper temperature, it is allowed to escape from the lower part of the lower

Fig. 5.—Vascular nævus on the labium majus of an infant before treatment.

coils through small cocks with minute openings into the lower third of the container, which is a partial vacuum. The air escaping into the vacuum, and already very cool, rapidly expands, and becomes still colder. About two-thirds of the air escaping is lost, but one third remains as a liquid in the container, which can be drawn off through a cock as wanted, just like any other liquid.

Liquid air looks like water, and can be poured out of the container like it. When the finger is dipped in it and hastily withdrawn, it feels like water, but the finger comes out dry. When it is thrown on the floor it strikes with a thud, and instantly disappears as steam without dampening the floor. Viewed through the glass container it seems to be boiling quietly, and a delicate vapor floats over the mouth of the flask. The temperature of the air is — 252.5° C. So great is its expansive power in its effort to return to its natural state as atmospheric air it can not be corked up, as it would blow to atoms anything but the strongest steel cylinders. It is handled in what is called a Dewar bulb, a flask of glass so blown that there is one flask inside of another with a vacuum between. This is placed in a case, and packed all round with wool to prevent too rapid evaporation of the air. Its mouth is partially closed with a loose plug of absorbent cot-

Fig. 6.—The patient shown in Fig. 5, six months after the application of carbonic snow.

ton so as to allow of the escape of a small amount of vapor that is constantly coming off from the liquid. In this way a litre of the air may be kept for several days.

Carbon Dioxide or Carbonic Acid Gas is a gaseous compound of carbon and oxygen. It is made

in various ways, commonly by the action of hydrochloric acid on calcium carbonate, and purified by passing it through a solution of permanganate of potassium. It is a colorless gas, about one and a half times as heavy as air, with a feeble odor, and slightly acid taste. Its temperature is — 31° C. By

Fig. 7.—A case of epithelioma before the application of carbonic snow.

mixing it with ether and allowing the mixture to evaporate the temperature can be lowered to — 100° C. The gas is caused to liquefy under pressure with the aid of a cooling device, somewhat like that used in making liquid air. As it is under a pressure of only 900 pounds to the square inch and has nothing like the expansive power of liquid air it is delivered in steel cylinders. These are familiar to many of you in connection with soda water fountains. At one end of the cylinder is a brass adjustable valve operated by a socket wrench at the tip. The vent hole, which is at one side of the valve, is covered with a brass hexagonal cap. Opposite the vent hole is a safety valve covered with a round, knulled, perforated cap set to 1,800 pounds pressure. This valve is never to be tampered with, as it preserves the drum, and prevents undue pressure, explosions, and danger. In point of fact there is no danger in handling and keeping these cylinders. The manufacturers of the gas assure us that they have never had an accident with the thousands of cylinders they have sent out. As they are tested by hydraulic pressure up to 3,700 pounds, and as they are charged under a pressure of only 900 pounds, when the gas liquefies, it is easy to understand why no accident has occurred.

Methods of Application.—1. Liquid air is best applied by means of swabs made by wrapping absorbent cotton around pieces of wood. These can be made of any size or shape required to fit any lesion. Care must be had to use a sufficient amount of cotton to absorb enough liquid to produce the effect desired. In very small lesions we have to freeze a little more than otherwise would be necessary since very small swabs would not hold enough to do effectual work. The swab is dipped into the liquid, when withdrawn it is given a sharp jerk to remove superfluous liquid, and then it is applied to the part to be treated with pressure varying according to the effect we wish to produce.

2. Carbonic Acid Snow. In order to make snow for freezing purposes the cylinder containing the gas must be placed on a stand, or on a rack fastened to the wall, and at an angle of about 45 degrees. (See Figure 1.) This prevents the freezing of the valve, and permits the making of a soft and easily moulded mass of snow. It is well to have the valve end of the cylinder fastened firmly by a strap, as at times the valve is hard to turn. The cap covering the vent hole is now to be removed, and all is ready for the making of the snow. This forms on account of rapid evaporation of the gas through some porous material, wrapped around the vent.

There are several ways of gathering the snow. Dr. Pusey first used a chamois leather bag made by taking a piece of the leather, making several turns with the straight edge about the vent hole, and folding the piece back on itself. Dr. Hubbard, after a number of experiments, invented the apparatus which we now use almost exclusively. It consists of a piece of brass pipe of diameter great enough to fit round the vent hole. This is cut longitudinally in two parts, which are then united on one side with a piano hinge. It is perforated with a number of holes, and covered with chamois leather on both surfaces. The leather is two or three inches longer than the tube, so as to allow of its being turned back over it. The best results are obtained by wrapping a little absorbent cotton about the vent hole and placing a plug of the cotton in the further end of the tube before applying it to the vent hole. When ready to make the snow the chamois bag, or the Hubbard apparatus, is applied to the vent hole and the gas is allowed to escape by turning the nipple at the extreme end of the cylinder with the small wrench that comes with it. The air is allowed to escape slowly at first, and then more rapidly. At first there is a whizzing sound as of gas escaping under pressure; sometimes there is some sputtering and jerking of the tube or bag, which need give no concern. A bluish gas will be seen to escape, and in five or ten seconds fine flakes of snow will blow through the

Fig. 8.—The patient shown in Fig. 7; the epithelioma has disappeared after the application of carbonic snow.

chamois. That is a sign that the apparatus is full of snow. Then the gas is turned off and the apparatus removed. It will be found to be full of snow. (See Figure 2.)

When the snow is gathered it may be moulded in any shape by working it in the bag or packing it

in molds made of sections of iron or brass pipe of different diameters. Pusey advises the use of square shaped molds so that if more than a single area is to be frozen the edges may not overlap. For very small lesions ear specula make admirable molds. There is no difficulty about removing the

Fig. 9.—Nævus pilosus in a girl of 6 years; before treatment.

snow from the molds as in a few moments by evaporation at the sides the mass grows small enough to allow of pushing it out. If the snow is properly made in the Hubbard apparatus it will be compact enough without packing it in molds, and can be whittled down with a knife to any desired size or shape. Though the temperature of the snow is about − 78° C., it can be safely handled and manipulated if the fingers are protected by the chamois or a glove. When drawing the gas, for further protection of the hands, it is well to wrap a towel about the apparatus.

The Effects of Freezing.—Juliusberg cut out pieces of frozen skin for microscopical examination. Bowen and Towle summarize his findings in their report as follows: He found that freezing caused an occlusion of the blood vessels with subsequent anemia, necrosis, and atrophy of the epithelium in proportion to the intensity of the application.

There is no difference in the effect on the tissues whether we use liquid air or carbonic acid snow except that the air being more than three times as cold the effect is more rapidly attained by the former. The Mayo brothers found that mixing ether with the snow made it freeze more rapidly, which we might expect from the investigations as to temperature of the gas as already quoted. The snow is not to be mixed with the ether or chloroform, but the cone is to be lightly dipped into it just before it is applied to the skin.

In order to avoid confusion we will speak hereafter only of the effect of freezing with the snow.

With a sizzling noise the place of contact with the cone is instantly frozen hard, turns white, looking like white ice, and when tapped with a firm object it gives a sound like that of striking wood. The depth of the freezing will depend upon the amount of pressure used and the length of time of the contact. Thus we have the effect under control. It is difficult to give exact rules as to the length of time and the amount of pressure to be used in a given case. As in many other procedures experience guides the operator. As a working rule it may be stated that the more superficial the lesion is the shorter should be the time of freezing and the less the amount of pressure. Ten seconds with moderately firm pressure will freeze the part stiff. In a few moments the part will thaw, there will be a zone of redness about it and in a short time vesicles will form on it. In a day or so a slight crust will form, which when it falls will leave a scarcely perceptible scar. In a short time this may disappear entirely. Twenty or thirty seconds with firmer pressure will freeze still deeper. Thawing will take place more slowly, and in the course of six to eight hours will be followed by the formation of a tense bulla. The bulla dries into a dry crust and leaves a slight scar. With longer applications and with deeper pressure the effects are exaggerated. Thus with freezing of about fifty or sixty seconds there follows a bulla that dries down into a dry eschar that does not fall until about three weeks. The dryness of the crust in all cases is a peculiarity of the action of the snow or air. The scars left by deep freezing are always soft and pliable, more beautiful from a cosmetic standpoint than those left by any other destructive agent.

It is rarely necessary to apply the snow for more than thirty seconds. If it is first dipped in ether or chloroform the time must be reduced as the effect is increased. All crusts should be removed before freezing. Whitehouse advises covering lesions on mucous membranes with a thin piece of gauze to avoid freezing the swab fast, when liquid air is used. He has found that the reaction is less marked in senile and ill nourished skins than in those that are firmer and well nourished. As a rule it is best not to repeat the freezing, where repetition is necessary, until the effects of the first freezing have been recovered from. In very many cases only a single freezing is required. In all the ten years during which we have been employing this method of treatment we have never seen any untoward effects. At times and in places where there is looseness of the tissues, as in the neighborhood of the eye, there may be a great amount of swelling so that the eye may be closed. This is uncomfortable for the patient, but absolutely without danger. The frozen part should be left alone after freezing. If a bulla forms there is no harm in pricking it. Crusts must not be removed, but allowed to separate of themselves. When they fall a sound skin is left.

Fig. 10.—The patient shown in Fig. 9, after several applications of carbonic snow; child still under treatment.

Is this method of treatment painful? The freezing causes slight pain in some subjects, while in others there is no pain at all. If we could concieve of an instantaneous frost bite, as of the ears for instance, we could appreciate that the part would become numb so quickly that no pain would be felt.

The thawing out is painful; sometimes very much so. We have seen men and women shed tears and show evidence of pain while the tissues were thawing, and this pain may last for several hours. But it is not nearly bad enough to deter us from using the method, and may be greatly mitigated by the application of cold water.

It may be asked which is better, liquid air or carbonic acid snow? If the air could be always obtained it would be preferable on account of the ease with which it is applied, the rapidity with which it acts, and its comparative painlessness. But the supply of air is most uncertain. For months we have been unable to procure it. The advantages on the side of carbonic acid snow are: (1) It is always to be had. A cylinder can be kept in one's office for the making of snow at any time, or the snow can be made at any drug shop where soda water is sold. (2) Lesions, no matter how small, can be frozen with it. Unlike liquid air we do not need to freeze any larger surface than necessary, as we can whittle the mass down to any size required.

Therapeutics of Freezing.—It is as a destructive agent that freezing is used for the most part. Dr. White used liquid air for the stimulation of ulcers, and for producing anesthesia for surgical purposes. For the latter purpose it acts quicker than ethyl chloride. It is sufficient to produce only a superficial freezing. Some have used this anesthetic action to quiet the pain of zoster. Here the cold is applied to the spine. We have not tried this.

Dr. White advocated its use for the treatment of boils and carbuncles. He applied liquid air for this purpose in the form of a spray from a bottle with a cork perforated to let two glass tubes pass through. When the finger was placed over the shorter tube, the air came in a fine stream of spray from the other tube that went down into the liquid. In this way the air was forced into the openings of the carbuncle or boil, and the surface was slightly frozen.

As many of Dr. White's early experiments were made at the Vanderbilt Clinic, and as freezing in one form or another has been employed there ever since, it is probable that our experience has been greater than that of any other clinic. We have, unfortunately, very incomplete records of the hundreds of cases we have treated. Our experience has impressed upon us certain definite conclusions.

We feel sure that the *best* treatment for *lupus erythematosus* is freezing. Every case of this most intractable disease has been cured when the patient has given us the opportunity to complete the treatment. The disease is capricious, and recent cases often yield to other remedies and disappear without a scar. It is best then to try other simpler remedies in recent cases. But in chronic patches, where there has been more or less deep destruction of tissue, freezing is the remedy of choice. Of course, it does scar, but the scar is soft and pliable, and the disease is sure to scar of itself. We have seen many patches heal with a single freezing. In this disease it is not necessary to freeze deeply. When the cone is dipped in ether, fifteen seconds is usually enough.

Nævi of all sorts are amenable to freezing. Superficial vascular nævi are readily destroyed in from fifteen to fifty seconds. Angiomata likewise yield readily, though they sometimes require a second application. If of large size so as to form tumor-like growths, sometimes the color is removed but the tumor remains. Port wine marks do not respond as well as other forms of vascular nævi. Pigmentary nævi are easily removed. Hairy nævi also must be frozen deeply, using firm pressure for one or two minutes, so as to destroy the hair follicles. Though they may have to be frozen several times, at last the result is a brilliant one. No other method gives better results, and all other methods require far more time.

Epitheliomas especially of the rodent ulcer type, we have come to regard as a special field for freezing. A cure is effected more rapidly than by any other form of caustic, and with less pain, and the scar is of the best. In them the pressure must be firm, and the time of freezing from half a minute to a minute and a half, depending upon the depth of the ulcer and the thickness of its walls. Other forms of the disease may be cured by it, and in inoperable cases it should always be tried. *X-rays* do not stand in comparison with liquid air or carbonic acid snow in the treatment of superficial epitheliomas. They are very slow in producing a cure, and their use is always attended with dangers. Freezing is rapid in results, and its use is entirely devoid of danger. We have been able to follow some cases for years without recurrence. In other cases recurrence does take place, as is apt to be the case after any form of treatment. But it is an easy and expeditious matter to destroy the small points of the relapse.

Keratosis senilis is readily removed by freezing. *Warts, papillomata, tatoo marks, powder stains, hypertrophied scars, keloid, tuberculosis verrucosa cutis, chloasma,* and *scrofuloderma* have all yielded to freezing.

We believe that Dr. White's application of freezing with liquid air as a therapeutic agent is one of the most important of our time. We commend the use of freezing as a most reliable method of treatment. We believe that we will learn before long how to use it not only for purposes of destruction but also of stimulation, and thus greatly broaden its field of usefulness.

THE EARLY DIAGNOSIS OF SYPHILIS AND THE TECHNIQUE OF EXAMINATION FOR THE SPIROCHÆTA PALLIDA.*

By WILLARD J. STONE, B.Sc., M.D.,
TOLEDO, OHIO.
ATTENDING PHYSICIAN, ST. VINCENT'S HOSPITAL.

In 1905 Schaudinn,[1] and later Schaudinn and Hoffmann, described the constant presence of the *Spirochæta pallida* in luetic lesions. Since that time an enormous amount of work has been done, and the apparent distinct relationship of this organism to both congenital and acquired forms of the disease seems definitely proven. This organism does not fulfill all the requirements of the four rules of Koch as regards its etiological connection with the disease, since it cannot be cultivated on artificial media. Nevertheless, practically all authorities are convinced of its definite etiological relationship. It has been pointed out by Hoffmann[2] and others that the same state of affairs holds true for the malarial protozoan and the leprosy bacillus, still no one questions the etiological relationship of these organisms to their respective disease processes. In relapsing fever, until very recently, the organism (*Spirochæta obermeieri*) could not be cultivated on any of the ordinary media in use. Morris, Pappenheimer, and Flournoy[3] have recently been able, however, to secure a certain amount of multiplication in citrated blood.

Metchnikoff and Roux[4] were among the first to demonstrate experimentally that syphilis could be inoculated in apes. More recently Neisser, through experimental work carried on in Java during the past two years, has been able to produce successive lesions by inoculation from one generation to another, demonstrating the pale spirochete in all.

The organism is present in the secretion of the primary sore and in the neighboring lymph glands. In the secondary stages it has been constantly found in a large proportion of cases. In the secretion of mucous patches, fissures on the tongue, and luetic condylomata it is particularly abundant. It has been obtained from the spleen during life, and Schaudinn and others have obtained it from the blood in secondary syphilis, although as a rule it can be found in the blood only with extreme difficulty. It has been repeatedly found in the inflammatory zone near the periphery of gummata by Schaudinn, Hoffmann, and others. In the congenital form, its presence has been repeatedly demonstrated in the liver, spleen, lungs, blood, heart, suprarenals, pemphigoid bullæ, etc., following the early work in congenital forms of the disease, by Buschke and Fisher and by Levaditi.[5]

For the demonstration of the organism, Goldhorn's or Giemsa's stain, or the method of Levaditi may be used. Levaditi recommends a slightly modified silver impregnation method used by Ramon y Cajal for staining nerve fibrillæ as satisfactory for the demonstration of the spirochete in the tissues. Thin slices are fixed in 10 per cent. formalin for 24 hours, then washed in water for an hour; then submerged in 96 per cent. alcohol for 24 hours. The slices are then placed in 1.5 per cent. silver nitrate solution in a dark incubator at 37° C. for 72 hours. After washing in water for about 20 minutes to remove the excess of silver, the tissue is placed in the following: Pyrogallic acid, 4.0; formalin, 5.0; distilled water to 100.0, for 48 hours in a dark bottle at room temperature. After washing in water for a few minutes the slices are put through increasing strengths of alcohol and imbedded in paraffin. The cut sections should be thin. The spirochetes appear black. Weak carbolfuchsin makes a good contract stain for the tissues.

For simple staining of secretions from the primary sore, mucous patches, secretion obtained by puncture of lymph glands, etc., or by expression of secretion from papules or bullæ, the stain recommended by Giemsa (modified Romanowsky) has been found generally satisfactory. (It is best to obtain the Giemsa stain in solution ready for use.) The films are fixed in absolute alcohol for ten to fifteen minutes and dried between filter papers; drying in the air or careful agitation of the film over the flame answers the same purpose. The stain is diluted with distilled water (one drop of stain to 1 c.c. of water and well shaken). The solution may be made alkaline by the addition of a 1 per cent. solution of potassium carbonate in the proportion of 1 drop to 10 c.c. The stain should be applied for from 30 minutes to one hour; washed thoroughly in water, dried between filter papers and mounted in balsam. The pale spirochete takes on a distinct pale red color and the spiral twistings are distinct and well preserved; the *Spirochæta refringens* is stained blue and the spirals are flatter and wave-like.

The stain of Dr. L. B. Goldhorn likewise gives good results. The entire staining process requires about one-half minute. The unfixed cover glass dried in the air is covered with the prepared dye, which should be kept anhydrous, and is poured off after three or four seconds. The cover class is immediately dipped slowly into water for three or four seconds holding the preparation side downward to avoid precipitation. It is then washed and stood upright, not flat, to dry. Gentian violet solution heated on the cover glass or slide also gives good results (Herxheimer). For staining the flagellum present at each pole of the organism, Löfflers flagella stain is satisfactory.

For examination of fresh unstained secretion, the oil immersion 1/12 (Zeiss Apochromat. 2 mm, aperture 1.3 or 1.4) with compensation ocular No. 6 or 12 may be utilized. The preparation should be as thin as possible (a little physiological salt solution may be allowed to flow under one edge of the cover glass if too thick), and the edge of the cover glass may be rimmed with vaselin to prevent evaporation. The illumination should be intense, and the Abbé condenser lowered to the point of clearest

*Read before the Academy of Medicine of Toledo and Lucas County, Ohio, December 11, 1908.

definition. As a rule, the ordinary chromatic oil immersion 1/12 does not give clear definition for this work. A large Welsbach or Auer gaslight is better than sunlight.

The rays may be concentrated and focused on the microscope mirror by using between the source of

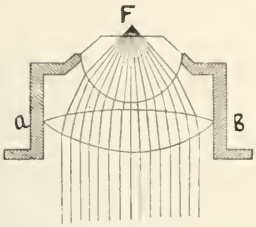

Fig. 1.—Abbé Condenser; A-B represents aperture of condenser for direct light showing convergence of rays on field F (after Novy)

light and mirror, an ordinary convex magnifying glass of about 10 cm. diameter. The spirochetes should be sought for about the edges of cell particles, leucocytes, or erythrocytes to which they frequently adhere by their thread-like prolongation or flagellum. Rimming the cover glass with vaselin to exclude the air, as has been shown by Hoffmann and Beer, makes it possible for the organism under these conditions to preserve its motility for weeks. As a rule, however, unless kept warm, it loses its motility in an hour or two. The above described method requires practice on the part of the observer and is much inferior to the method described below for examination of fresh unstained material by means of the dark-field illuminating condenser which can be applied to any microscope. The principle of this condenser is such that a system of plano-convex lenses so reflects the light that *reflected* light only comes through for the illumination of the object. The field itself is dark, while the object to be examined is illuminated. It is in this contrast that the definition of the object is clearly outlined. The degree of illumination within certain limits depends upon the size of the diaphragm which cuts out the direct rays, and the intensity of the light.

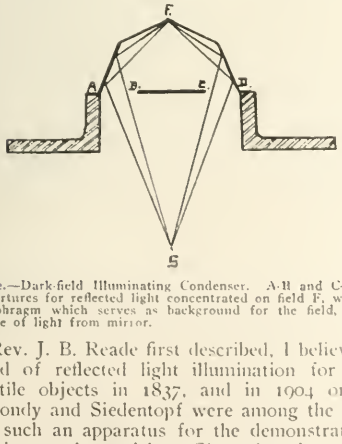

Fig. 2.—Dark-field Illuminating Condenser. A-B and C-D represent apertures for reflected light concentrated on field F, while B-C, the diaphragm which serves as background for the field, is dark: S, source of light from mirror.

The Rev. J. B. Reade first described, I believe, this method of reflected light illumination for feeble refractile objects in 1837, and in 1904 or 1905 Zsigmondy and Siedentopf were among the first to apply such an apparatus for the demonstration of ultramicroscopic particles. Since that time various European optical firms have improved and perfected the instrument, under the name, "Dunkelfeld-Spiegelkondensor."

In the ordinary Abbé condenser the principle involves the illumination of the field and object by concentration of the rays of *direct light* on the field F, as follows:

In the new dark-field illuminating condenser reflected light only is concentrated upon the object which is intensely illuminated, while the field is dark (see Fig. 2).

By this system of illumination ultramicroscopic particles, living bacteria, and organisms of feeble refractile power, such as the *Spirochæta pallida*, are more clearly defined than by any other method of examination in vogue. As mentioned above the degree of illumination depends upon the size of the diaphragm, interposed between the source of light and the object, and the intensity of the light. In the ordinary Abbé condenser (Fig. 1), the degree of direct illumination depends upon the size of the aperture A-B, while in Fig. 2, showing the condenser for indirect reflected rays, the illumination depends upon the size of the outer aperture A-B and C-D; the greater the outer aperture A-B and C-D, the greater the illumination. Conversely, the greater the inner aperture B-C, the less the reflected ray illumination.

The earlier Reichert condensers gave the inner

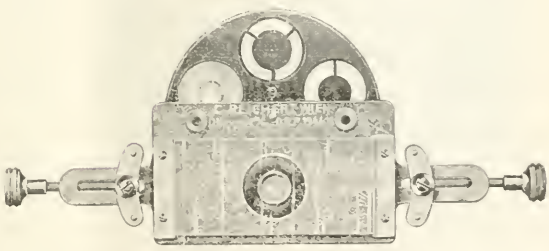

Fig. 3.—Dark Field Illuminating Condenser. Type Fb

aperture B-C a numerical value of 1.1, while the new Leitz instrument also has a value of 1.1. Such values necessarily restrict the outer aperture through which the rays of reflected light pass, making it necessary to employ for best results a source of light of comparatively greater intensity, such as the arc-lamp. Carl Reichert[6] of Vienna, in order to render the use of the instrument possible with ordinary Auer or Welsbach gas lamps, or with the Nernst electric lamp, has been able to reduce the value of the inner aperture B-C from 1.1 to 0.85. A reduction much below the value of 1.0 would allow direct rays of light to pass through, a result which would impair the utility of its purpose. The reduction from 1.1 to 0.85 increases the value of the outer aperture for reflected light, *i. e.* gives more light upon the image, and the ordinary inverted Welsbach gas light or the Nernst electric lamp (preferably the former) gives excellent results, especially if a concentrating mirror is interposed between the light and the reflecting mirror. The Nernst 32-watt lamp gives, with 110-volt direct current, about 160 candle power.

The Leitz instrument, which has a value of 1.1 for the inner aperture, gives, in my experience, excellent results in spirochete examination if a light of greater intensity, such as the arc lamp, is used. In my work I have used the Reichert Spiegel-Condenser new type, Fb, a cut of which is given below.

This can be attached to any microscope stage, and costs in Europe $20. A smaller instrument, type F (Fig. 4), is also made by Reichert, costing $10. In the use of either of these, the Abbé condenser is removed from the microscope. The large instrument, type Fb, is more convenient to use, since it has a revolving disk, which gives any numerical value for the inner aperture depending upon the size of diaphragm revolved into position, from 0.85 to 1.45, and, in addition, a ground glass disk and a small Abbé condenser which can be revolved into position instantly for examination of stained tissues or bacteria, urinary sediments, etc. The smaller instrument, type F, must be removed and the Abbé condenser put on for ordinary microscopic work, which necessitates, in ordinary laboratory routine, certain inconvenience.

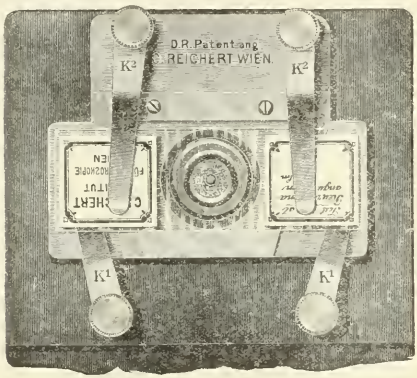

Fig. 4.—Dark Field Illuminating Condenser. Type F.

Technique.—From a suspected primary lesion a smear is made after cleansing with a cotton swab, securing, if possible, some of the serum which exudes as a result of irritation with a small curette or the platinum wire. A drop of warm salt solution is placed on a thin slide. The secretion obtained by curette or wire is mixed with the drop and a clean cover glass inverted over it. Or one of the enlarged inguinal glands is seized between the fingers and its center punctured with a hypodermic syringe, through which a drop or two of gland juice is aspirated. A smear is prepared in much the same way from a mucous patch, bulla, or condyloma latum. A drop of cedar oil is interposed between slide and condenser, not between cover glass and lens. The No. 7 Leitz dry objective with No. 3 ocular, or, as I have found best in my work, the No. 8 or No. 12 compensating ocular is used. The No. 7 objective with compensating ocular No. 12 or No. 18, while requiring more intense illumination, gives better results, since the size of the organism is at least doubled, *i. e.* a magnification equal to a combination of 1.12 oil immersion and No. 3 ocular. If the oil immersion 1.12 is to be used with the dark-field condenser, the lens should be returned to the manufacturer to be fitted with a diaphragm which has been found necessary for this work.

The spirochetes, if present, are seen as illuminated spiral-like organisms, moving in wave-like motions across the field. In some preparations they are very abundant, while in others some search is necessary to find them.

A little practice will serve in differentiating the pale spirochete from other organisms present in the specimen. In mouth lesions, tonsillar plaques, and tongue fissures one must differentiate it from *S. buccalis* and *S. dentium*. In fresh smears kept warm by allowing a little warm salt solution to flow under the edge of the cover glass from time to time, the motility of all of these forms can be preserved for an hour or two. As a rule, however, *S. pallida* loses its power of locomotion sooner than the others.

In a fresh specimen the organism is very active, the spiral windings very thin and sharp, well differentiated, and regular. The flagellum at the end of *S. pallida* is very thin in proportion to the thickness of the body, while the end of the body is thicker than in most of the other forms. The flagellum of *S. pallida* is also longer as a rule than in other forms. The characteristic spiral movement of *S. pallida* is forward and backward, and when it attaches itself to a leucocyte it remains quiet often for a considerable time, even in fresh preparations. Hoffmann has stated that the other forms attach themselves less often to cells present in the smears. At times *S. pallida* has a distinct sideway pendulum movement. It is more feebly refractive to light than the other forms commonly found, and the windings or spirals are more acutely bent. The other spirochetes met with most commonly are *S. balanitidis* and *S. refringens*.

If one is careful to cleanse the lesion with a pledget of cotton wound on an applicator before obtaining the material on a sterile platinum wire, and especially if the lesion is irritated with the wire after such cleansing, so as to secure an exudation of "irritation serum" from the deeper layers of tissue, the commoner forms of spirochetes are less seldom found. As a matter of fact, I have in the past few months examined the secretion from a considerable number of unclean mouths, from so-called "canker sores," stomatitis and lesions of the gums, pyorrhœa alveolaris, and the secretion of the glands about the glans penis, from small ulcers about the cervix and cervical lacerations, without in any instance finding an organism closely resembling the *S. pallida*. The *S. balanitidis* and *S. refringens* will more or less frequently be found in the secretion obtained from the glans penis, vulva, or vagina, but the differentiation of these organisms is not as a rule difficult.

The Early Diagnosis of Syphilis.—Hoffmann[7] has shown by inoculation experiments that *S. pallida* is present in the blood three weeks before the manifestation of the roseola. The blood of a suspect was inoculated into an ape with the result that there developed at the point of inoculation a typical papule which contained *S. pallida*.

By the time the primary lesion has developed sufficiently to become noticeable the infection has already reached the lymph channels of the skin papillæ, with free access to the larger lymph streams. In fact, at the time of the original infection, within a few hours, in all probability the organisms have reached the lymph channels of the skin papillæ. Neisser has shown by excision experiments on apes that this probably occurs within 8 or 10 hours. As Hoffmann has stated, the fact that such rapidity of lymph infection occurs speaks against any other mode of transmission than the lymph stream. The spirochete does not, so far as present experiments show, reach the blood-vessels or begin to wander through delicate capillary walls until somewhat later. Probably the first changes that result locally after the invasion of the finer lymph channels are in the form of a lymphangitis and perilymphangitis with

obstruction of lymph flow and edema. This becomes more marked throughout the incubation period, about three weeks, and during the period of development of the organism in large numbers, until finally, through the inflammatory process set up by them in the walls of the small veins and capillaries, an obstructive endophlebitis and arteriolitis results. Necrosis of the connective-tissue cells is a concomitant part of the process with an abundant emigration of lymphocytes into and about the area of infiltration. This is soon accompanied by a certain amount of hyperplasia with the new formation of delicate blood vessels, as pointed out by Ehrmann. The characteristic hardness of the initial lesion is in part due to the swelling of the surrounding lymph vessels as a result of the obstructive lymphangitis, in part as the result of edema and the filling of the tissue spaces with lymphocytes.

The swelling of the neighboring lymph glands, so far as present knowledge goes, probably is merely the result of a protective hyperplasia against the invasion of the organism and its poison, not because the glands serve as particular breeding grounds for multiplication. The neighboring glands, however, do contain *S. pallida* in large numbers, coincidental with the development of the primary lesion, and thence they find their way into the lymph circulation and, somewhat later, the blood. They reach the blood stream before the development of the so-called secondary manifestations, probably by two or three weeks. They have been found in large numbers during the very early periods of the disease in the spleen, suprarenals, and bone marrow.

The Importance of Early Diagnosis and Early Treatment.—Since we now have a method at our disposal by means of which an early diagnosis can be made from any suspicious genital, lip, or mouth lesion, it goes without saying that such a method should be utilized in every case before passing judgment as to the harmlessness of the process. Negative findings do not of necessity mean that the process is not luetic, any more than one or two negative sputum examinations for tubercle bacilli indicates that the case may not be tuberculous. Positive findings, however, at once make clear the nature of the condition, and a large percentage of primary sores, mucous patches, condylomata lata, and indurated lymph glands adjacent to the primary lesion will show *S. pallida* by the method outlined above.

Neisser, Hoffmann, and others have recommended with much wisdom the excision of the primary lesion as soon as the *S. pallida* is found, with the idea in view that at least an important focus of spread to others and to the general circulation of the patient himself will be eradicated. In view of the fact that the spread from the primary lesion to the lymph circulation takes place comparatively early in the ulcerative process of the primary sore, such excision, if practicable, should be done early. In many cases we may not be able to see that excision is carried out with the removal of a fair amount of healthy surrounding tissue. The next best thing to do will be thorough, actual cauterization, preferably under an anesthetic, followed by a mercurial ointment. Where such a procedure cannot be carried out, the use of a mercurial ointment, such as a 10 per cent. white precipitate ointment or a 10 per cent. calomel ointment, may be recommended. The patient should also be brought under the constitutional effect of mercury as soon as possible. It is no longer necessary to wait for the development of so-called secondary symptoms, since, by getting the patient as early as possible under treatment, the rapid multiplication of the organisms may be controlled and the development of secondary symptoms ameliorated.

COLTON BUILDING.

WHY MASTOIDITIS IS SOMETIMES MISUNDERSTOOD.*

BY EMIL AMBERG, M.D.,
DETROIT, MICH.

THE misunderstanding of what is generally called mastoiditis acuta is responsible for grave and sometimes fatal errors. For this misconception must be blamed, not only the hesitator, through whose wavering an easily controllable process of destruction becomes difficult, and sometimes impossible to be redressed, but also the injudicious physician who advises immediate operation in all suspected cases, advice which is promptly resented, and which is proven in many instances to conflict with the foretold outcome of the disease. Both men are conscientious and medically more or less well educated; why, then, are we confronted with such a discrepancy of opinions?

This difference of opinions must be attributed to the fact that both are right at times. Some will take no chances, and know that an operation is generally much less dangerous than perils involved by waiting. Many have the fear of the unknown and magnify in their minds the risk of a skilfully performed operation. Leaving aside, however, those fortunately rare cases of fatal outcome, even in spite of comparatively early operation, a better understanding can be reached by giving more weight to the pathophysiology of acute inflammations of the temporal bone, so far as it is known.

This pathophysiology of diseases of the temporal bone is of more recent date. Undoubtedly the rules of general surgery apply also here, but the construction of the temporal bone presents considerations of its own which are of vital importance. First of all, we must not forget that the mastoid process is only a part of the middle ear. Furthermore, as Politzer has shown, the pneumatic cells of the mastoid process contain pus in cases of purulent tympanitis. If the presence of pus in the mastoid cells would always mean an acute mastoiditis with affection of the bone itself, or if this presence of pus would always lead to serious complications or death, the whole question could be solved very easily.

Why does the presence of pus in the mastoid not always lead to serious consequences? G. Boeninghaus gives the following explanation: "In most cases this empyema heals as smoothly as the empyema of the tympanic cavity. . . . In other cases (according to Bezold, in 9 per cent.) the inflammation reaches the osseous structure of the mastoid process and destroys it. Pathologico-anatomically it is an osteitis rarefícans simplex. The periosteum

*Read January 12, 1909, before the Northern Tri-State Medical Society, in Ann Arbor, Mich.

of the osseous trabecula, the outer layer of the mucous membrane of the mastoid cavities, swells up by hyperemia and infiltration (Scheibe, 1904) to twenty times its former thickness. This inflammation progresses to the marrow through the vessel channels of the osseous trabecula, which hereby loses its fat-cells and becomes granulation tissue. The resorption of the osseous trabecula (Scheibe) now progresses from the periosteum and from the marrow in the usual manner by lacunary melting (Howship's lacunæ) with the aid of giant cells (osteoclasts). This resorption of bone is introduced and accompanied by hyperemia and infiltration of the inner mucous membrane, which points to the lumen of the mastoid cavities, and which swells up, to from forty to eighty times its thickness, to flap-like granulations, which keep their epithelium only at their bottom (Scheibe). After the osseous trabecula have been resorbed these granulations form one single mass together with the granulating bone-marrow. This may sometimes fill up the entire newly formed cavity. The melting of the corticalis proceeds also lacunarily from the periosteum, from the outer periosteum as well as from the mucoperiosteum. In the corticalis, however, we find the Sharpey's fibres (Scheibe) instead of the narrow spaces with its osteoclasts, those connective tissue fibers which penetrate from the outer periosteum into the corticalis just as in any other bone. The irritating cause which leads to osteitis seems to be only pus, which stagnates or is entirely retained in the meshwork of the cavities, because as soon as the outflow of pus is regulated by spontaneous or artificial perforation, the resorption of the bone ceases (Scheibe), contrary to what occurs in osteitis rareficans tuberculosa, and the opposition of new bone starts in the ordinary manner through osteoblasts, but only in a comparatively modest way. We have no real analogy of this osteitis of the mastoid process in the whole pathology of the osseous structures. During recent years, the short and proper term, mastoiditis acuta, has become familiar in place of osteitis rareficans simplex, and rightly displacing the older terms caries and empyema of the mastoid process, since the term caries carries with it the idea of continually progressing, tuberculous destruction of the bone, and the term empyema means only pus retention in a natural cavity, and not in a cavity created, to a great extent, through the melting of the walls."

Bezold says: "The cause of the fact that a perforation occurs and that no absorption of pus in the cells takes place must be sought for not in the nature, nor in the quantity, nor in the virulency of the pyogenic organisms, but in special anatomical conditions: superficial position of the cells, thinness and dehiscencies of their walls, and especially the pressure of single giant cells. . . . The formation of osteoclasts and their bonewrecking occupation comes to a standstill as soon as the pus is evacuated, and a layer of cells containing one large nucleus takes their place on the walls of the diseased spaces. They are the osteoblasts which at once form osteoid substance, and this later on becomes ossified all around and in the focus. At a greater distance from the focus of suppuration the occupation of the osteoblasts and the formation of osteoid tissue begin long before the evacuation of the pus. . . . The natural opening of these cavities does not occur as the surgeon dictates it, that is, exclusively toward the outside; the enlargement of the cavity takes place eccentrically in all directions."

Koerner remarks that the main difficulty consists in deciding whether we have before us a still resorbable empyema of the pneumatic cavities, or a melting process in the bone. He adds: "The later the spontaneous perforation ensues, or the later the paracentesis has been made, the greater is the probability of the co-affection of the bone. When perforations in the posterior upper quadrant have repeatedly been blocked from the inside by hypertrophy of the mucous membrane, or by granulations, so that retention of pus follows which betrays itself by pain and fever, we have to do with a co-affection of the bone. Especially suspicious are the high-situated nipple and volcano-like perforations. In profuse suppuration which does not cease in from two to four weeks, I have always found destruction in the bone. If the suppuration, however, decreases even slowly, it does not prove a co-affection of the bone, even if it lasts longer than four to six weeks. As already mentioned, many acute middle-ear suppurations show, in the beginning, swelling of the periosteum and tenderness of the mastoid process on pressure. So long as pus has not found a free outflow through the drum membrane, these phenomena only prove that the coating of the pneumatic cavities participates in the inflammation. If they do not disappear immediately after the perforation of the drum membrane and after the establishment of a free outlet, a suspicion that the bone is also affected is awakened. If they make their appearance only during the time when the outflow of pus through the drum membrane is not interfered with, the co-affection of the bone is certain."

Koerner makes the very significant remark regarding a fact which I also have observed in my practice, as no doubt all of us have, that the general condition shows an improvement when the inflammation of the ear improves. He says: "The physician who observes and treats not only the ear but also the patient can recognize hereby the progressing process in the bone before outer signs present themselves in the mastoid process."

A physician of Detroit accidentally saw, in the beginning of July, 1908, in a summer resort in Canada, Master J. C., of P., 14 years old, whose general condition appeared to him to be very bad, and he advised immediate consultation. The boy had had measles in April. Both ears were discharging in May, very freely. He had pain all over his head, which somewhat disappeared the day before he consulted me. For two days he complained of pain behind the left ear. The discharge from his ear was less in the last two weeks than it had been before. I found the mastoid very tender on pressure. On July 14, after incising the drum membrane, I opened the mastoid extensively in Harper Hospital. The dura of the posterior cranial fossa was exposed by the destructive process to a large extent; the cortex was soft, and yet this patient traveled and went to a summer resort in order to regain his health, upon advice of his physician. Recovery was prompt.

In cases of this nature the term mastoiditis may be misleading. It is apparent that a suppuration which reaches beyond the cells of the mastoid process proper cannot, and therefore should not, be called a mastoiditis. For instance, an involvement of the retrolabyrinthine cells cannot be called mastoiditis, because these cells are located in the petrous bone. Zuckerkandl (in Schwartze's Handbook) says: "Besides the pars mastoidea, also the part of the petrous bone located between the semi-

circular canals and the sulcus sigmoideus falls into projection of the pneumatic spaces. This harbors the mastoid antrum, which passes only exceptionally beyond the anterior border of said venous channel in the horizontal projection. Only that lower portion of the antrum which reaches in its descent into the mastoid process comes within the region of the sulcus sigmoideus, which is mostly surrounded by mastoid cells."

It would be correct, I think, to establish a clearer conception of the destruction by calling the affection by its proper name. A detailing nomenclature might be too lengthy, *e. g.* "tympano-mastoideo-petritis," or "tympano-mastoideo-squamitis," etc. It would simplify matters if we would call "tympanomastoiditis" a process in which the tympanum and mastoid cells alone are involved, whereas a process in which other cells than the mastoid cells participate might be called "temporitis" (from os temporale).

In connection with this question we must be aware that we must consider numerous groups of cells which are at times encountered in the temporal bone. In Escat's "Technique Oto-Laryngologique" we find an excellent tabulation of these cells. He mentions ten distinct groups, namely: 1. The zygomatic cells. 2. The cells of the tegmen tympani. 3. The cells of the squama. 4. The cells of the main body of the mastoid process. 5. The cells of the tip of the mastoid process. 6. The cells around the facial ridge. 7. The cells above the lateral sinus. 8. The cells below the lateral sinus. 9. The cells between the lateral sinus and the facial ridge; and 10, the cells toward the rear of the petrous bone. To these must be added—11, the other perilabyrinthine cells (Politzer). 12. The so-called paramastoid cells which are sometimes found —I do not think always, but sometimes very pronounced—posterior to the tip of the mastoid process, practically forming a second tip. The cells medial of the incisura mastoidea may be identical with the cellules sus-sinusales (see No. 8) mentioned by Escat. 13. The cells of the upper wall of the external canal. 14. The cells between the antrum and the meatus, near the upper posterior quadrant of the drum membrane. (A periosteitis or subperiosteal abscess of its inner-upper portion causes the pathognomonic symptom of sagging of the upper posterior wall of the canal [Koerner]. 15. The cells on the roof of the antrum. 16. The cells on the floor of the tympanic cavity. 17. The cells around the entrance of the Eustachian tube. 18 The cells on the rear of the canalis caroticus (Politzer). While not belonging to the temporal bone, we must further mention—19. Those pneumatic cells of the occipital bone which are found sometimes (according to Politzer), and which are connected with the mastoid cells (Hyrtl's pneumatic occipital bones).

Politzer gives the following résumé: "The pneumatic cell spaces originate from the mastoid antrum; they reach backwards to the sutura occipitalis, they surround the lateral sinus and the emissarium Santorini. Downward they reach the tip of the mastoid process, the inner surface, and the incisura mastoidea. Upward and forward they reach the linea temporalis and the root of the zygomatic process. They completely surround the auditory canal with the exception of the anterior lower wall. Inwardly they reach sometimes the tip of the pyramid. They frequently surround the labyrinth on all sides and are also directly adjacent to the bulb of the jugular vein, the osseous part of the Eustachian tube, and the posterior part of the canal for the carotid artery."

In connection with this schedule it may be well to remember that the fatality of some of the cases after tympanitis may be explained by the appearance of a meningitis originating from the retrolabyrinthine cells.

These retrolabyrinthine cells were the subject of a very instructive discussion in the *Verein für Chirurgen Berlins*, on Feb. 24, 1908. Passow, speaking of the cases of unsuccessful opening of the mastoid antrum, said, in part: "In acute and subacute cases of otitis which show the tendency to become chronic or to diminish the power of hearing, the subject of the opening of the antrum is generally reached smoothly if the indication is properly met, and if the operation is carried out technically correctly. Furthermore, a cure does not take place if pus is not evacuated from all cells, *i. e.* from the cells below the tympanic cavity, or in the pyramid, or in the petrous bone, or around the labyrinth. Very frequently the suppuration heals spontaneously in these, but sometimes it carries with it the gravest complications by propagation and penetration of pus into the labyrinth and into the cranial cavity." Of this Passow cites some instances in which a meningitis developed and led to death during a few hours. Therefore, he recommends looking for all diseased parts during the first operation.

Jansen said in part: "The cause of these fatalities is to be found in a deep extradural abscess emanating from retrolabyrinthine cells. Fortunately the disease process does not leap in bounds into the deeper parts. As a rule, we have before us a process proceeding *per continuitatem*."

When we furthermore take into consideration the fortunately rare cases of acute affection of the temporal bone which lead rapidly to death, we must confess that we are far from being able to give an absolutely certain prognosis in a number of instances. The element of uncertainty, however, does not allow us to preserve a hesitating attitude in doubtful cases.

Koerner makes the following statement: "When one is convinced, after considering everything that has been said about the symptoms and diagnosis, that we no longer have in the mastoid process an empyema but that the bone also is diseased, then the postponement of the operation cannot be justified. When only the probability of the affection of the osseous structures is present, it is better to operate than to wait, because the operation in these acute cases carries no other danger than that of the narcosis, provided the technical skill is sufficient, whereas hesitation not infrequently causes the death of the patient through intracranial complications."

Of course, the question of anesthesia needs careful consideration. In this connection it may be well to consider latent tuberculosis more than has been done heretofore. Perhaps we can recall in our own practice, or in the practice of our friends, one or another case in which the narcosis cannot be excluded entirely as at least a contributing cause, if not as a main factor, in producing serious consequences in this respect.

Conclusions.—1. At the present time it is impossible to reach an absolutely certain decision regarding the necessity of surgical interference in some cases of affection of the temporal bone.

2. In most cases the groups of symptoms, and in

many cases the presence of one or two marked symptoms, make surgical interference appear imperative.

3. The danger of general inhalation anesthesia in any operation, especially in persons suffering from tuberculosis, should not be forgotten. The employment of local anesthesia might be more thoroughly tested in cases in which the general anesthesia is contraindicated.

4. The temporal bone contains numerous groups of cells which may come into consideration in an affection of the same, and therefore the term "temporitis" may be a better name than "mastoiditis," which is sometimes misleading.

5. The construction of the temporal bone is such that a process can go on in the depth without betraying itself by very plain symptoms; marked symptoms may appear suddenly, and in some instances they pronounce the death sentence of the patient.

REPORT OF TWO UNUSUAL CASES OF APPENDICITIS.*

By ALEXANDER NICOLL, M.D.,

NEW YORK.

ASSOCIATE PROFESSOR OF SURGERY, FORDHAM UNIVERSITY SCHOOL OF MEDICINE; VISITING SURGEON TO FORDHAM HOSPITAL; CHIEF OF THE SURGICAL CLINIC, ST. VINCENT'S HOSPITAL.

During the past summer, in a series of 190 operative cases, 75 of which were laparotomies in which the appendix was investigated either as the pathological organ for the removal of which the operation was done, or incidentally during operative

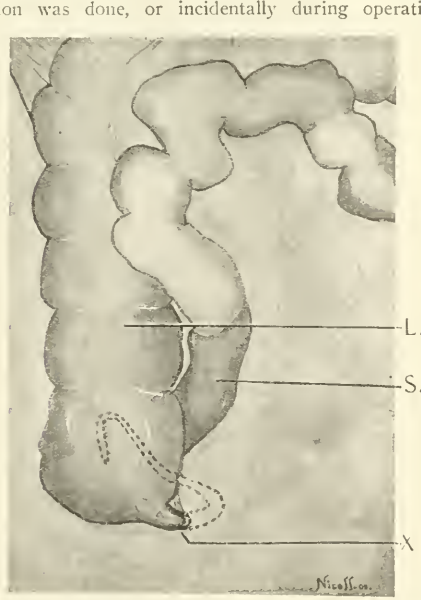

Fig. 1.—Extraperitoneal appendix; diagrammatic; L. I., large intestine; S. I., small intestine; X, point at which appendix loses peritoneal investment and turns into retroperitoneal space; dotted line represents the extraperitoneal portion of the appendix.

measures directed toward some other intraabdominal structure, two very unusual appendicular conditions were encountered which seem to me to be of sufficient rarity to justify description. The first of these cases was one in which there was severe and general infection of the peritoneal cavity, together with obstruction of the small intestine, and in spite of prompt operation the patient died of general peritonitis. The second case was not associated with any such severe infection, and the patient made a perfectly satisfactory and rapid recovery. The histories of the cases are as follows:

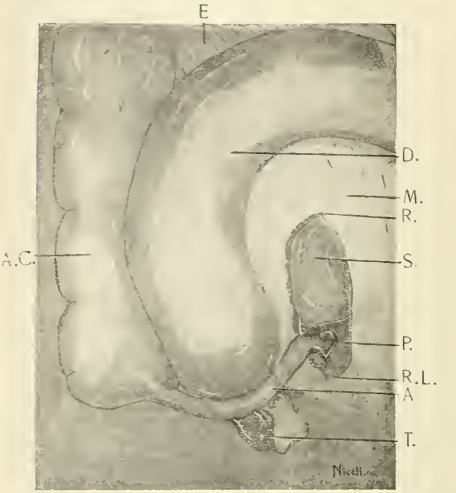

Fig. 2.—Intestinal obstruction due to constriction of small intestine by gangrenous appendix; diagrammatic; D, distended small intestine above point of obstruction; M, mesentery of small intestine; R, upper end of gap in mesentery of small intestine; S, portion of small intestine seen through gap in mesentery; P, posterior abdominal wall to which end of appendix is adherent; RL, lower end of gap in mesentery of small intestine; A, appendix surrounding loop of small intestine and constricting it; T, recurrent portion of loop of small intestine below the point of constriction by appendix; AC, ascending colon; E, posterior surface of transverse mesocolon.

Case No. 646.—The patient was a hard-working, muscular man of about twenty-seven years of age. He had had the ordinary diseases of childhood, which had left him without sequelæ of any sort. He stated that he had never had any serious abdominal trouble at any time. He had never, to his knowledge, received any severe blow upon the abdomen nor had he had any attack similar to the one which brought him to the hospital for treatment. Three days previous to admission he was seized suddenly with pain in the pit of the stomach, cramps all over the abdominal area, and vomiting. He did not recall that he had been noticeably constipated for the few days immediately preceding his attack. The most persistent feature of the first few hours of the attack was vomiting. During the two hours immediately following his seizure he had several watery movements from the bowels. The vomiting and pain continued and increased in severity, and he no longer had any movement from the bowels. Thinking that he had eaten something that disagreed with him, he took several doses of salts and followed this up with more cathartics. Enemata were given without producing any movement of the bowels, and the pain and vomiting persisted. During the next two days his symptoms persisted and grew gradually worse. On the third day he was admitted to the hospital.

On admission his temperature was 102.8°; pulse, 130, and of a distinctly peritoneal character, and respirations were rapid and typically thoracic. He

*Reported before the Society of the Alumni of St. Vincent's Hospital, October 14, 1908.

was profoundly shocked. The abdomen was greatly distended and tender. He referred his pain to the lower part of the abdomen immediately below the umbilicus, and it was in this region that the tenderness was most pronounced. The patient vomited several times while in the ward, the vomitus being bile-stained and not fecal. Enemata were given without result, not even gas being passed from the rectum. A blood-count taken just before operation showed 17,000 leucocytes to the cubic millimeter.

Operation.—The abdomen was opened in the median line below the umbilicus. Pus was found free in the lower part of the abdominal cavity and was of the thin grayish-yellow variety associated with low resistance. The small intestines bulged from the peritoneal cavity and were enormously distended, dark red in color, filled with fluid, and "meaty" in appearance. Midway between the point at which the appendix is usually located and the median line the constricted portion of the intestine was found and this constriction was produced in a most peculiar and unusual manner. The appendix, which was about four and one-half inches long and gangrenous at its distal end, extended inward and upward, encircling a loop of small intestine and constricting it; beyond the constricting portion the appendix ran through a gap in the mesentery and was adherent, at the distal extremity, to the posterior abdominal wall. (See Fig. 2.)

The gap in the mesentery was most peculiar in appearance and unlike anything I have ever seen It was not a rent but an actual loss of substance, about two and one-half inches long by an inch and one-half wide. It had more of the appearance of a wound made after death than a condition occurring in the living body as the result of trauma or disease. Incidentally there was no history of either trauma or disease in this case. The edges of the gap were slightly ragged, and neither reddened, indurated, nor bleeding. There were about it none of the signs of inflammation which might be expected from its relation to the acutely inflamed appendix. The appendix was not adherent to the mesenteric border, but was adherent to the posterior wall of the abdominal cavity.

The loop of small intestine was withdrawn from the loop of the constricting appendix without any very great difficulty, and was found to be in good condition at the point of constriction. The appendix was removed by ligature and cautery. Gauze drainage was inserted into the pelvis, in the right and left iliac fossæ, and the abdominal wound was closed with through-and-through sutures of silkworm gut. The patient's condition was such that layer suturing was out of the question. In spite of stimulation the patient did not rally, and died about ten hours after operation.

Perhaps as peculiar an appendicular condition occurred in another case with a much less severe infection. The following is a brief résumé of the case.

Case No. 999.—A woman, aged thirty, was taken with the usual signs of an acute catarrhal appendicitis and was treated by means of ice-bags, rest, etc. She came to me in the interval following her attack, and upon examination I found a point of tenderness on the right side of the abdomen half way between the site of a normally located appendix and the position of the gall-bladder. Incidentally examination by vagina disclosed a right-sided parovarian cyst. In consideration of the high location of the point of tenderness a retrocecal position of the appendix seemed probable.

Operation.—The abdomen was opened in the median line below the umbilicus in order easily to reach and to remove the pelvic cyst. The cyst was removed and a portion of cystic ovary was resected. The appendicular region was then investigated, and after some difficulty in locating the base of the appendix this was brought into view. The base of the appendix was ligated and cut through with the cautery and the mesenteriolum, which was about a quarter of an inch long, was ligated and divided. The appendix was found to be in normal position for about one-half inch of its length and then turned sharply backward, dipped through the posterior parietal peritoneum, losing its peritoneal investment, ran upward in the retrocecal areolar tissue for two inches, and then turned abruptly upon itself and ran downward and outward for an inch and one-half. In order to remove the appendix it was necessary to incise the posterior parietal peritoneum. This was done, and the appendix was drawn from its bed of fat. The small peritoneal wound was closed with fine catgut and the abdomen was closed in the usual manner with layer sutures. It was rather interesting to note that only the intraabdominal portion of the appendix was inflamed, the extraperitoneal portion being undeveloped, not inflamed, with a lumen for only a short distance, and tapering off into a solid fibrous cord. This patient made a rapid and complete recovery.

123 West Seventy-fourth Street.

GONORRHEAL CONDITIONS IN WOMEN.*

By ANDREW J. LOVE, M.D.,

NEW YORK.

In speaking to you on gonorrheal conditions in women, I shall speak with special reference to gonorrhea as a cause of mutilation and sterility in women, and as a reflection of this disease in their male consorts. Up until a few years ago gonorrhea was regarded as an entirely local disease in contrast to syphilis. The physician looked upon it with a sort of indifference. A disease to be treated if a patient presented himself for treatment, otherwise it would run its course and get well of itself. Even to-day many of the laity regard gonorrhea in no graver light than they do a "bad cold," and think that a man who hasn't had it is a tenderfoot who is to be pitied. But since the warning of Noeggerath, in 1872, and the discovery of the gonococcus, by Neisser, in 1879, and in the light of recent research, gonorrhea in all its bearings is coming to be regarded as one of the most treacherous if not the most deadly foe with which our civilization has to deal.

Prof. Janet, in his "Social Defense Against the Venereal Peril," in speaking of its frequency says, "If we compare from a social point of view the importance of gonorrhea with that of syphilis, gonorrhea is to syphilis as 100 is to 1, not only from the standpoint of the number of persons attacked, but also from the standpoint of the gravity of the lesions and their perpetuity, which to-day gives to the surgeons three-quarters of their work and conducts finally, both men and women, to sterility."

Dr. Tabor Johnson emphasizes the importance and widespread influence of the gonococcus as a factor in disease and particularly in sterility. He says, instead of its being the woman who is at fault, in nine cases out of ten of childless mar-

*Read at a meeting of the Valentine Mott Society, December 29, 1908.

riages, as was formerly believed, it is probable that the man is at fault in far the larger proportion of cases; that gonorrhea is responsible for most cases of salpingitis and for specific endometritis.

The principal difference between gonorrhea in the male and in the female is one of anatomy, and this anatomical difference is accentuated in the female genitalia by the short urethra together with the opening into the peritoneal cavity through the Fallopian tubes. The gonococcus either takes lodgment in the urethra, infecting Skene's ducts, or finds cozy corners in Bartholin's ducts and glands or in the cervical canal.

In the majority of cases that present themselves early to the physician for treatment, the disease may be arrested by confining the patient to bed, keeping the bowels open, enjoining perfect cleanliness, and swabbing out the parts with some mild antiseptic. But as a rule this is not the case. As there is more or less leucorrheal discharge in women, a mild case of gonorrhea will be mistaken for the usual discharge; or the woman, from a standpoint of false modesty, will refrain from going to the doctor until the acute stage is past. The discharge gradually subsides, all of the symptoms improve, and she takes comfort in her false security. It is several weeks or months after this that the doctor is consulted. Then the picture is entirely different, and its treatment is another story. The cocci have burrowed deeper into the cervical glands or passed higher into the cavity of the uterus, setting up a specific endometritis; or have passed through the uterine walls, invading the periuterine tissue, with abscess formation, infiltration, and agglutination; or have passed out through the Fallopian tubes, destroying the ciliary cells of these structures, or caused sacculation and abscess formation in the tubes, effectually destroying their lumen; or have attacked the ovaries with consequent cystoma, abscess, prolapse, and fixation with the partial or complete destruction of function. All cases, however, do not follow such a violent course, for there may be every degree of invalidism from a chronic endocervicitis to a complete perversion of the functions of the uterus and adnexa. Edgar reports several cases in which the disease had given no evidence of passing higher than the cervix and in that location was apparently well. These women became pregnant, and everything went well until after confinement, when an acute attack of gonorrhea lighted up with the result of infecting the body of the uterus, tubes, and ovaries. The subsequent salpingitis blocked the tubes, resulting in sterility, constituting the class known as "one child sterility" cases.

Then there are others who contract gonorrhea early in pregnancy which subsides in from four to six weeks. The woman goes on to full term without having trouble. After confinement reinfection occurs which ends in sterility. Almost all of these cases become sterile after one child, and if they become pregnant, almost, or never, go to full term. The placenta becomes infected in places where the nutrition is disturbed, or specific metritis so interferes with the circulation that the ovum is arrested in development with subsequent abortion. In the event that a child comes to full term it is, as a rule, handicapped with an inferior constitution, ekes out a miserable existence, and soon succumbs to some intercurrent malady.

It is a disputed point as to whether the gonococcus enters the pelvic cavity through the uterine walls or through the tubes. There is abundant evidence of both. The organisms are found deeply imbedded in the body of the uterus as well as in the tube itself. But whether they enter through the tubes or through the uterine walls, the end results are about the same. For both paths lead but to sterility.

In the tubes the irritation causes inflammation and infiltration. They are usually sealed at one or both ends, plastic material is poured out around the point of greatest infection, with more or less pelvic peritonitis. There have been reported a few cases of general peritonitis, but this is rare. When the gonococci become sealed up in an abscess-cavity, they soon die. In other situations, however, their virulent action on the pelvic tissues so reduces the vitality that the colon bacillus and the staphylococcus find easy entrance, giving rise to a mixed infection. These last-named bacilli spend their force and soon die, but the gonococcus imbeds itself in the tissues and goes into a sort of slumber only to be aroused by sexual excitement, overexercise, traumatism, or some other condition, reducing the vitality of these tissues. Then new areas of inflammation develop. The ovaries are often covered with inflammatory tissue, which makes ovulation either imperfect or impossible. The tubes are sacculated with pus, or are distorted in such a manner as to close up the lumen. The irritant action of the bacteria on the lining membrane of the tubes destroys the ciliary or hair-like cells and makes transmission of the ovum into the uterus impossible.

Gonorrhea is the greatest cause of sterility in both male and female; in both, it is probably a greater cause than all others combined. Noeggerath, as early as 1872, read a most prophetic paper before the American Gynecological Society on "Latent Gonorrhea," which brought down great odium on his head. He claimed that gonorrhea, in the male as well as in the female persists for life in certain sections of the organs of generation, notwithstanding its apparent cure in a great many instances. "There is a form of gonorrhea," he said, "in both sexes, called latent gonorrhea, which may infect a healthy person with either acute gonorrhea or gleet. Latent gonorrhea in the female manifests itself as acute, chronic, or recurrent perimetritis, or ovaritis, or as catarrh of certain sections of the genital organs; finally about 90 per cent. of sterile women are married to husbands who have suffered from gonorrhea either previous to or during married life." It may be contended that 90 per cent. is too high, which is probably true, but other writers, Neisser, Crolax, Gruenwald, and others, place it from 40 to 70 per cent.

A committee of seven appointed by the Society of Prophylaxis of Venereal Diseases, in this city, to investigate gonorrhea in women, reported that 30 per cent. of all married women treated by gynecologists in private practice had gonorrhea, contracted from their husbands.

It is a pathetic picture to see a sweet and virtuous young woman, who has been recently married, come with a story like this: She has been married about five months; previous to her marriage she had had no trouble with her menses, but for the last three periods she has been suffering with her genital organs, and her complaint continually gets worse. She first had a general malaise following the menses, which lasted several days. Then she had a greater and longer flow than usual and had

to remain in bed a week or more, and she is now tender over her ovaries and is suffering from an abundant leucorrhea. The story is plain, and you at once know that she has been married to a man who had gonorrhea a short time before his marriage, but the discharge having ceased and active symptoms having subsided, he thought himself cured. She looks up to him as a paragon of virtue and righteous manhood, but he leads her to a bed of disgrace and infertility, and to a life of decrepitude.

It is stated by Noeggerath that 80 per cent. of all men between the ages of 18 and 28 either now have or have had gonorrhea. It is appalling to contemplate the number of men, who marry innocent wives, and who have latent gonorrhea which they transmit to them, and both cut short their fruitfulness and make them invalids for life

It is claimed that in some individuals one attack of gonorrhea gives a greater or less immunity, a sort of vaccination, and that gonorrhea in prostitutes is the cause of their sterility. A recent investigator found that out of a number of well prostitutes, whom he examined, 30 per cent. had gonorrhea, and that out of a number who presented themselves for treatment for various illnesses 75 per cent. proved to be gonorrheic. These women usually have the disease in its latent form. They are in a sense vaccinated by the gonotoxin, so that they may cohabit with men who have the disease in a virulent form and yet do not contract it. But on the other hand, if such a woman should have intercourse with a man who has not had gonorrhea, he would contract it in all its fury. Moreover, a man who has had gonorrhea one or more times, and in whom there is an apparent cure, may not take it from a prostitute who is likewise suffering, but may convey the same to his innocent and trusting wife, whose vagina is virgin soil. This is but a part of the tragedy, for the climax is reached only when he accuses her of infidelity.

In man, too, gonorrhea is a fruitful source of sterility. Recent investigations not only prove that gonorrhea, as a disease, must stand up as a general one, that it causes inflammation of the joints, muscles, endocardium, and the like, but that in all cases in men who have bilateral epididymitis it causes them to become sterile. A married woman under such circumstances not only has a husband who is sterile, but from the same cause, transmitted to her during his early career, impregnation and childbearing for her are impossible.

According to some authorities, 75 per cent. of all women operated upon for pelvic disorders are victims of gonorrhea, and 60 per cent. of all abdominal surgery would cease if it were not for gonorrhea. It is not possible to state accurately just what per cent. of these cases are gonorrheal, because in from 30 to 40 per cent. of pus cases operated upon the pus proves to be sterile, but most abdominal surgeons are running their percentages of gonorrheal pathology in the pelvic cavity higher.

Another fruitful source of sterility is due to vulvovaginitis in little girls. Sara Welt-Kakels observed in her clinic at Mt. Sinai Hospital in ten years, from 1893 to 1903, 190 cases, being 1.6 per cent. of all children admitted. The largest number occurred in children between two and five years of age.

L. Emmet Holt reports his investigations in the New Babies' Hospital, in this city, in 1902. One case of vulvovaginitis was inadvertently admitted. In a very short time eleven cases developed, with a yellow purulent discharge and the characteristic symptoms of this stubborn disease.

It is often communicated from mother to child while sleeping together. A marked demonstration of this kind occurred in Posen, Germany, in 1870, when 236 little girls, ranging from six to fourteen years were taken ill, within fourteen days, of vulvovaginitis. They had all been bathing at a public bathhouse, and it was necessary for from two to four girls to bathe in one tub.

The gonococcus has the effect of arresting the development of the genital organs in these children, and consequently in them we find the infantile uterus, long, thin, and imperforate tubes, and ovaries that do not mature a normal ovum. These girls grow up to be women who are hopelessly sterile.

It is not here, according to Darwin's theory, the survival of the fittest, for in all these cases, both in the young married women and in the little girls, the gonococcus is plucking our sweetest flowers, and is sapping the best blood of the nations.

3440 Broadway.

TWO INTERESTING CASES.

EXTENSIVE PERITONITIS; PERFORATION OF THE RECTUM.

By James H. Stevens, M.D.,

Boston, Mass.

These two cases are believed to be worthy of report because every case of general peritonitis recovering is of interest to the surgeon, and is always open to more or less question, and the second case is interesting etiologically at least. The folds of peritoneum are many, and I confess that personally I always feel that cases of general peritonitis which recover are, in the vast majority of cases, open to doubt. Every surgeon has had a number of cases which he classes as general peritonitis in which recovery has taken place; but it seems to me that the entire question is one of what we call general peritonitis, and unless the case comes to the necropsy table I do not see how any surgeon can be absolutely certain that his case is one of actual general peritonitis. He knows that a great amount of peritoneal surface is involved; it certainly appears to him at operation a generalized condition, but the folds of peritoneum are many, and in the face of what appears a generalized process he is not prone to push into every recess of peritoneum to satisfy himself if it, too, is involved in the process.

The following case, I think, illustrates this and also illustrates what I believe to have been a great mistake in the treatment of these cases in the past, namely, the use of large quantities of salt solution to flush out the abdomen.

Case I.—A clerk, aged 48, who had never before suffered from symptoms referable to his appendix, was taken with pain in his abdomen and was seen twelve hours after the initial symptoms. The usual signs of peritonitis were present; a temperature of 103°, a rigid abdomen, constipation, etc. He was operated upon sixteen hours after the initial attack at the Elliot Hospital. The intestines were distended and covered with pus and exudate. The appendix was swollen to the size of half a fist and absolutely gangrenous. It was lightly adherent to the posterior abdominal wall, but nowhere else was there any attempt on the part of the peritoneum to wall it off by adhesions. The wound was enlarged

upward and downward to give a free opening. Pus was present outside the ascending colon and under the liver, every coil of intestine which could be seen was bathed in the same purulent exudate, and the hand carried to the left side was followed on withdrawal by quantities of pus. So far as any one could see, it was a generalized process and was considered as such by both myself and my associate. The appendix was tied off and large gauze and rubber tissue wicks were used for drainage (no tubes being used), one in the pelvis, one to the posterior abdominal wall where the appendix had been held, one running upward outside the ascending colon, and one carried to the left between the coils of intestine where usually I never place a drain. The abdomen was not washed out, the worst of the intestinal coils which presented themselves were lightly wiped with gauze, and the wound was left wide open. The patient was placed in Fowler's position. Neither one of us expected him to recover, and his convalescence was a protracted one. The entire deep fascia as far as the median line sloughed away. He developed a septic pneumonia, but recovered finally, and was discharged, and is to-day well, barring a very large abdominal hernia. It is unfortunate in this case that no culture was made, and therefore the offending organism is not known. As so many recoveries from general peritonitis, due to the pneumococcus have been reported, and especially on account of the lung complication, it is possible that this case was due to this cause, but the especially interesting features of the case to me, and the only reason for reporting it, were the rapidity and virulence of the process and the treatment without another incision and without flushing out the abdomen, together with the drainage by rubber tissue wicks inside of tubes.

Was it a general peritonitis? This simply depends on what one calls a general peritonitis and whether such a condition can be diagnosticated absolutely outside the autopsy room.

Case II.—This presents what is, at least to me, a unique cause of traumatic perforation of the rectum. The patient, a young and fleshy woman, was taking a rectal enema of oil, using a hard rubber hand syringe with a two-inch nozzle, in the semi-sitting position. She lost her balance and fell, pushing the entire syringe with the exception of the ring handle, into her rectum. The pain was excessive, but the syringe was easily withdrawn and as the patient did not find blood, following its withdrawal, she became convinced that no injury had resulted. The pain in the lower abdomen continuing she took an enema of a quart of salt water, which was partly expelled. During the night, following the accident, the pain continued; she vomited, but being so much better the following morning, she went to her work (that of a bookkeeper), but was compelled to lie down some of the day.

Twenty-four hours after the accident I was called to see her. Her temperature was 102°, her pulse 100. Her abdomen was somewhat distended, tympanitic, but with little rigidity. The pain was better, but was still present, and on vaginal examination was pronounced on lifting the cervix. She was sent to the hospital. A rectal examination, without ether, disclosed a rent in the right anterolateral wall of the rectum (knee chest position) four to four and a half inches above the sphincter. On November 23, at the Elliot Hospital, twenty-six hours after the initial injury, I opened her abdomen, disclosing the internal tear low down in the pelvis, extending between the uterorectal folds. There was a little dark blood-stained exudation in the cul-de-sac and a local peritonitis. The operation was without special interest and without special difficulty, save for the distention of bowel, due to lack of preparation, and a very fat abdominal wall. The rent was sutured and the wound drained with a cigarette drain.

On December 11, while progressing satisfactorily, she suddenly sat up in bed with a sharp pain in her left chest, and became cyanotic and dyspneic. Her respirations were 45 per minute and the pulse ran up to 160 and was barely perceptible, while edema of the lower lobe of the left lung developed rapidly. A diagnosis of probable pulmonary embolus of small extent was made and her convalescence was a long and stormy one. The drainage wound closed satisfactorily on January 7, and she was discharged on January 26, 1909.

The case seems of sufficient interest to report, on account of the manner of the injury and from the fact that a large enema was taken immediately following, without a more serious peritoneal involvement twenty-six hours after the injury.

261 Beacon Street.

Drainage of General Purulent Peritonitis in Women by Way of the Perineum.—A. Giuliani says that the dictate of surgery as to the point at which drainage should be made to be effective is that the opening should be at the most dependent point. When we drain a general peritonitis with collections of pus in the *culs-de-sac* we are doing an unsurgical thing because the pus cannot escape freely in this way. For drainage he advocates the perineal route. Here the opening is made at the most dependent point and the pus is often pushed out as if by a force from above. The chief disadvantage is the difficulty of doing this operation rapidly which is experienced by those unaccustomed to this route while the good of the patient demands a rapid operation. In men drainage should be made by way of the sacrum or parasacral region or by the lumbar region. Perineal drainage may be made by way of Douglas' *cul-de-sac* or by a combined abdominoperineal method.—*Lyons Médical.*

Traumatic Rupture of Large Intestine; Operation; Recovery.—W. H. Battle reports the case of a woman of 33 years run over by an omnibus. She was admitted to hospital and in ten hours had rallied sufficiently to be operated on. A diagnosis was made of rupture of the large intestine, with commencing inflammation along the course of the descending colon. An incision was made through the outer part of the sheath of the left rectus. Examination of the abdominal contents led to the belief that there was a rupture of the gut behind the peritoneum with a communication directly into the peritoneal cavity. A second incision was made backwards through the abdominal wall at a right angle to the primary cut just below the ribs, and further incision of the peritoneum to the outer side of the flexure gave access to a space containing soft fasces, which had escaped from a hole in the bowel the size of a penny at or below the splenic flexure of the colon; the space containing the extravasated fecal matter extended upwards into the retroperitoneal tissue behind the spleen and could hardly be cleansed, for the fecal matter was ground into the cellular tissue. The opening in the bowel was closed with interrupted silk sutures which did not enter the lumen, the torn edges being inverted. The peritoneum, which had been packed off during the treatment of the bowel, was now cleansed, and some ounces of blood-stained offensive fluid removed from the pelvis. The wound was partly closed, the peritoneum being sutured off from the parts affected by the injury, a tube was passed into the splenic region, a plug placed over the sutured portion of bowel and brought out at the posterior extremity of the transverse incision. The woman recovered after a somewhat prolonged convalescence. The author says that symptoms of rupture of the large bowel following trauma are as a rule the same as with similar conditions in the small bowel and gives some statistics concerning cases similar to his own which have been treated in St. Thomas's Hospital, to which his patient was admitted.—*British Medical Journal.*

A NEW THEORY OF SURGICAL SHOCK.

THE value of experimental physiology as a faithful handmaid to surgical progress has been so amply demonstrated within the past few years, that it hardly needs illustrative comment. Among the many problems that have presented themselves for investigation in the laboratory, those associated with surgical shock have been among the first to challenge attention. The epoch-making researches of Crile on surgical shock are still fresh in the mind. That the last word has not yet been uttered upon the subject, is evident from the recent interesting contribution from Yandell Henderson (*American Journal of Physiology*, April 1, 1909).

As the result of a painstaking series of investigations in his laboratory at Yale, this author contributes an entirely new and original hypothesis on the causation of shock following laparotomy, and offers suggestions as to its prevention and relief. The gist of his argument is that surgical shock is the result of a diminution in the amount of carbon dioxide in the blood. This condition, which is known as acapnia, is brought about in a number of different ways. The stimulation of afferent nerves causes accelerated breathing (hyperpnea), which in turn causes a diminution in the CO_2 content in the arterial blood. Hyperpnea is also brought about by the inhalation of ether, which is a respiratory stimulant. The cessation of peristalsis, which is a well-known phenomenon following abdominal section, and which is generally regarded as a manifestation of surgical shock, is essentially the result of inhibitions. The acapnia is a factor in the central and reflex inhibition of which the splanchnics are the efferent paths. The exposure of the viscera to the air causes an exhalation of CO_2 and a local acapnia, which is a factor in the peripheral inhibition. Henderson believes that general acapnia from hyperpnea, and local acapnia from exposure are the initial causes of surgical shock after laparatomy. Furthermore, he maintains that when the loss of CO_2, both by way of the lungs and by direct exhalation, is prevented, and the blood gases are maintained at a nearly normal percentage, peristalsis can be directly observed in the stomach and in the small and large intestine.

That there is an actual loss of carbon dioxide from the surface of the exposed peritoneum, is not a mere conjecture, but has been subjected to definite volumetric determination. Thus, it has been found that the minimum rate of exhalation of CO_2 from exposed peritoneal surfaces is 0.15 to 0.20 c.c. per square centimeter, in the first half-hour. This is forty times the rate of exhalation of this same gas from the skin. That this rapid loss of carbon dioxide from the blood circulating in the peritoneal capillaries is closely associated with the intestinal torpor following abdominal section, is proved by the following fact: Exposing the abdominal viscera to a current of air at body temperature, and saturated with moisture, rapidly induces congestion, and a loss of tonus and mobility. Aeration of the viscera in this manner was an effective measure for the production of shock. On the other hand, it was found that the restoration of the body's supply of CO_2 was effective as a method of relief from all except the extreme stages of acapnial shock.

The practical bearing of these experiments is obvious. They indicate clearly that the CO_2 tension in the nerve centers and in the tissues and fluids of the body is a factor in the maintenance of tonus (in the broad sense of the word), of the same order of importance as temperature, oxygen supply, osmotic pressure, and the equilibrium of anions and cations. In the light of these investigations, one can readily perceive the importance of avoiding as much as possible the exposure of the peritoneal surfaces during operations on the abdominal cavity, which operations should, moreover, be terminated as rapidly as feasible.

THE WAR ON RATS.

THE first annual meeting of the Society for the Extermination of Vermin was held in London, on March 24, under the presidency of Sir James Chrichton Browne. It will be in the recollection of our readers, that this society was inaugurated in Great Britain rather more than a year ago, and that its object was to prevent the damage to property and the injury to health worked by the rat. It is stated that in England and Wales alone, every year rats do damage amounting to over £15,000,000. At this meeting the president enumerated some of the ways in which rats brought about death and disease: by boring communications from drains into dwellings; by gnawing through water pipes and gas pipes; by running over food with filthy, contaminated feet; by gnawing at food with filthy teeth; by causing loss of sleep and nervous trepidation; by carrying disease through the mediation of fleas. Professor Anderson, a great authority on the subject, has said that the damage done by rats in Great Britain was greater than the damage done by the cobra and tiger in India, while in India itself and in Australia it was now fully recognized that by means of rat fleas plague was propagated and that the only method of abolishing plague was to destroy the rats.

It is believed in England that rats can be stamped out as surely as leprosy and malaria have been stamped out there, and as yellow fever is being extinguished in tropical and subtropical America. The fact, however, must always be borne in mind that

the rat is no contemptible foe. It is one of the cleverest and most cunning of animals, and the manner in which it continues to evade the traps laid for it by its enemies and to live despite all the obstacles placed in its path, almost provokes admiration and pity for its fate.

The importance of the extermination of rats in India and in other places in which plague is present goes without saying. A flea is capable of holding in its stomach no less than 5,000 plague germs and as rats will carry a very large number of fleas and simply swarm in India, it can be easily understood how essential to the abolition of plague is the extermination of rats. Sufficient stress has not until recently been laid in this country on the prevention of rats landing from ships. Rather, perhaps, it might be said that enough importance is not paid to the destruction of rats on board ship. It may be a difficult, but it cannot be an impossible task to destroy rats on ships, and for all reasons of health steps should be taken to effect this object. In the latest annual report of the Public Health and Marine-Hospital Service, Surgeon-General Wyman urges an international crusade against rats on shipboard. He thinks it practically impossible to exterminate rats on land, but entirely feasible to rid the shipping of the world of them, and there is every reason to believe that his suggestion is practicable.

In Great Britain, owing in some degree to the energetic action of Mr. Rider Haggard, clubs have been formed in all parts of the country in order to destroy vermin. The results of this crusade have been exceedingly satisfactory up to the present time. A few protests have been raised against the destruction of rats by zoophil neurotics, but in the main the only objection has been in the form of doubts, in view of the magnitude of the task, regarding the feasibility of accomplishing its execution. There is room in America for the establishment of antivermin societies and clubs.

MEDICAL COMMISSIONS.

There must be something queer about the practice of medicine, or rather the practitioners of medicine, for we are repeatedly told that they are lamentably lax in their business methods and, in the same breath, that they are harpies, preying on the poor as well as the rich, and grafters of the most cunning stamp. It is without doubt true that the majority of medical men are poor financiers, subjectively and objectively; they are slow in collecting what is due them for honest work and as a necessary corollary they are often equally slow in paying what they legitimately owe. On the other hand the accusation is not infrequently made, especially against surgeons and specialists, that they are exorbitant in their charges for service and concerned more in securing prompt payment than in relieving the sick. It is natural, perhaps, that this accusation should lie rather against surgeons than internists, for the former have the appearance of doing more than the latter. The work of the mind is less tangible than that of the hand, and the workers themselves, as well as their patients, are apt to value it less highly. The management of a case of typhoid fever demands the exercise of as much mental acumen as the removal of a diseased appendix, and the anxiety of watching over such a case for days and weeks is greater and "takes it out" of the practitioner much more, but the surgeon often gets ten or twenty times the fee for his work, and it is paid promptly and with little murmur, while the general practitioner must wait long for his fee and maybe never gets it.

It is no doubt a sense of this inequality in compensation that has led to the custom of what is euphemistically called "dichotomy," or division of the fee between the surgeon and the general practitioner who has called him to operate upon his patient. It is hardly correct to call this a "custom," for we believe it is the exception, yet that it is occasionally done is certain. Where there is smoke there must be some fire, and there would not be so much discussion of the subject in the journals, in society meetings, and in private conversation did it not exist. In the abstract there is something to be said in favor of the practice, for it is analogous to what prevails in the business world where a commission is the legitimate reward to the man who brings together those who want a thing and the one who can supply it. But to those who regard the practice of medicine as something higher than pure business, a means of livelihood indeed, yet, above and beyond that, a mission for the relief of human suffering, the thought of taking what a man has paid for his life and dividing it behind closed doors with the physician whom he has trusted and whom he is also to pay for his services, is repulsive. A secret commission, even in Wall Street, is not regarded altogether with favor.

There is still another form of "graft" in the medical profession, or rather in its confines, that has recently been brought to public notice. We refer to the paying of a commission by a physician to the lay person who has sent him a patient. A prominent physician in Berlin was not long since exposed to public and professional scorn under accusation of this practice. According to a despatch to the *New York Times* he was charged by two physicians with bribing hotel porters and others to direct wealthy patients, principally foreigners, to his office. A number of other practitioners of lesser rank are under the same charge. At a meeting of the Berlin Medical Society, on March 24, the accused physician, who is president of the society, retired from office pending an investigation by a court of honor. He denied the charges and said that he merely paid the head of a Russian "institute for medical consultations" for his services as interpreter in the case of some wealthy Russian patients he had recommended, and that he gave some money to a couple of hotel "portiers," who were importunate in their demand for a commission, in order to get rid of them. We have no doubt he will be fully exonerated, but there are others in Berlin and elsewhere who, it is asserted, have a regular arrangement with hotel employees to send them patients. The accusers of Senator maintain

that the practice of paying commissions for rich patients has long been rife in the German medical profession.

This is the same in principle, of course, as the division of the fee between the family physician and the surgeon, but it seems somehow a little worse. We have never heard of its practice here and we question whether it exists, in this form at least, for here the large hotels all have physicians to whom they refer their ailing guests, and there is therefore no chance for competition and consequently no occasion for feeing the "steerer" of the suffering rich. Moreover we have not so many "fleeceable" travelers here in the shape of rich and money-spending foreigners to tempt the man of science from the path of rectitude and honor.

We cannot believe that either form of "graft" is common here or among physicians anywhere. Medical men are, as a rule, too neglectful of their material interests, and if we hear more of those who err on the side of being over solicitous in securing their just dues and more, it is because they stand out conspicuously as exceptions in a body of men concerned rather with the scientific and humane aspects of their life work than with its financial possibilities.

The Excitant of Trachoma.

The chronic inflammation of the conjunctiva, which goes by the name of trachoma and which is responsible for so many cases of partial or total blindness, has for a long time been the subject of earnest study by ophthalmologists. Its contagiousness classed it among diseases caused by parasites, but, though many microorganisms have been described as causative agents in the disease, no conclusive results have been attained. However, in the *Deutsche medizinische Wochenschrift* for March 25, 1909, Dr. Greeff presents a study of a new structure which he has found in the secretions and in the tissues of the affected conjunctivæ, and his findings go far to establish the fact of some causative relations existing between these structures and the disease. He has found, namely, that conjunctival cells and secretions in trachoma harbor a great many small rounded organisms, that are smaller than the smallest cocci known at present, that stain with difficulty by the Giemsa method, and that appear to be surrounded, when gathered into groups, by a distinct capsule. The mere finding of such structures would not, of course, establish their connection with trachoma. Greeff, however, has studied a great number of other diseases of the conjunctiva without ever finding any structures similar to the "trachoma corpuscles"; moreover, his pupils have succeeded in demonstrating the organisms in patients in various parts of the world. In addition, Halberstädter and Prowazek, working independently in Java, have discovered organisms in the diseased conjunctivæ of trachoma patients, that answer Greeff's descriptions of his structures. Greeff warns other workers of the difficulties with which the demonstration of these structures is surrounded, because of their small size and peculiar staining relations. Negative results, therefore, must not be considered as disproving his findings, at first, for training in looking for the "trachoma corpuscles" is necessary before they are easily found. As he gives, however, all the methods which have proved successful in his hands, and presents good pictures of the organisms, as well, control investigations by other workers may be expected to appear in a short time.

The Inhalation Treatment of Tuberculosis.

In medicine, as in other phases of human activity, we are apt to think that what is is best, and that old and practically abandoned methods must necessarily be useless. This belief prevails in spite of the teachings of history and with every swing of the pendulum or tilt of the seesaw we seem to be in the right place and the region whence we came and to which we are pretty certain to return looks from the distance darkened with the mists of error. The present method of treatment of tuberculosis by fresh air and rest and feeding seems rational and effective, and, so far as fresh air is concerned, it is without any doubt a great advance over the old-time method of living in close rooms carefully shielded from the night air and from any suspicion of draught. It is questionable, however, whether we have not swung too far from chemotherapy. We have done well to banish the sweet and nauseous cough mixtures which dammed back the secretions that do harm by their retention and which took away the little relish for food that remained, but we have become perhaps too pessimistic regarding the value of certain drugs that may repress if they do not kill the tubercle bacilli and pus germs which the unaided organism is powerless to combat. Creosote, for example, was at one time regarded with much favor in the treatment of pulmonary and laryngeal tuberculosis, and it still has its advocates. Beverley Robinson, writing in *American Medicine* for March, renews his plea for this remedy given internally and by inhalation, and contends that by its use the disease may often be arrested, even when a definite cure is not achieved. This drug can be employed in the ways suggested without interfering with the modern open-air methods, and when we consider the numerous failures of the latter in all but incipient cases it does not seem wise to reject altogether what many experienced physicians of the old school regarded and still regard as almost specific in tuberculosis of the respiratory organs.

Dr. Atkinson.

The older members of the American Medical Association will recall with affection Dr. William B. Atkinson who was for many years their active and untiring secretary—a man of most kindly and genial disposition and one of unfailing courtesy to all, never puffed up with a sense of the dignity of his office and ever ready to lend a willing ear to any member who had a question to ask or a misunderstanding to be settled. In a recent issue of the *Medical Standard* it is stated that this good man is now living at an advanced age (he is 77 years old) and in comparative poverty, and the suggestion is made that the Association grant him a pension of one hundred dollars a month. He served the Association faithfully and to the best of his ability, giving to it a great part of many of his best years, receiving an insignificant salary and few thanks from those at whose service he was. We agree with our contemporary that it would be a graceful act on the part of the Association to vote him a pension

"in recognition of the services he rendered during the many lean years when his personal influence meant much to the struggling Association," and we venture to assert that nothing which the House of Delegates may do at the Atlantic City meeting would receive more hearty approval of all the voiceless members than the granting of a pension to this beloved ex-secretary.

News of the Week.

The Care of School Children.—Acting on suggestions made by Dr. Henry D. Abbott, recently appointed medical inspector of the Bayonne (N. J.) public schools, the Board of Education of the city will install in each school scales for the measuring and weighing of all pupils at stated intervals. A card system will be introduced upon which the records of the pupils will be kept. Dr. Abbott has also advised the Board to abolish the practice of dusting with feather dusters, and to insist that soft damp cloths be used.

Inspection of Babies.—The Bureau of Child Hygiene of the Department of Health, beginning on April 15, will on the receipt of a birth certificate send one of its nurses to the home in which the child was born. The work is under the auspices of the Conference on the Summer Care of Babies, which represents various public and private agencies cooperating in the work.

Junior Sea Breeze.—The Association for Improving the Condition of the Poor announces that the summer camp for babies on the grounds adjoining the Rockefeller Institute will be reopened next month for the fourth season, with a considerable increase in the accommodations.

Public Health Law Amended.—Governor Hughes has recently signed a bill amending the public health law relative to the establishment of hospitals and camps for the treatment of pulmonary tuberculosis. The law requires persons, associations, or municipalities proposing to establish such an institution to file a petition with the State Commissioner of Health. The Commissioner and the local health officer are authorized to approve or disapprove the plan. In case of a deadlock, the matter may be submitted to another board composed of the Lieutenant-Governor, the Speaker of the Assembly, and the Commissioner of Health. Under the previous law the location of such institutions was in the discretion of the Board of Supervisors.

Tuberculosis Day and Night Camps.—The Boston Association for the Relief and Control of Tuberculosis has received a gift of nineteen acres of land in West Roxbury from Mr. J. M. Prendergast. The land will be used for day camps for tuberculous women, and for night camps for men suffering from the disease but still able to work during the day.

Venezuela Quarantine Over.—For the first time since the outbreak of bubonic plague in Venezuela last year, the quarantine in New York against ports of that country was lifted on April 6, with the arrival of the steamship *Philadelphia* from La Guayra.

Civil Service Examinations.—The New York State Civil Service Commission will hold examinations on May 1, 1909, for the following positions: Assistant bacteriologist to the State Department of Health, at a salary of $1,500; assistant physician to the Rome State Custodial Asylum, at a salary of $000, with maintenance. Applications must be filed on or before April 24, on blanks which may be obtained on application to the State Civil Service Commission, Albany, N. Y. The Commission requests that a postal card be used in applying for blank forms.

Better Ambulance Service.—A conference of various city officials was called at the Mayor's office recently, to consider the improvement of the ambulance service in New York. It was decided that this could be best accomplished by the passage of the Newcomb-Robinson bill, which is now before the Legislature, providing for a general Ambulance Board, and every effort will be made to urge this. In the meantime the Trustees of Bellevue and Allied Hospitals have decided to establish a temporary ambulance station somewhere on the upper west side to provide for the immediate relief of the district formerly covered by the ambulance service of the Roosevelt Hospital.

Disease in Free Lunches.—Dr. William H. Heath, pure food inspector of the Buffalo Department of Health, says that many cases of diseases of the throat and mouth can be traced to the free lunch counters, where the forks and knives are repeatedly used with only slight rinsings. He declares that the saloon keepers must stop serving free lunches or else provide a clean service for each person.

The Editorship of "The Lancet."—Dr. Squire Sprigge, who has been chief of the editorial staff of *The Lancet* for fifteen years, has been formally appointed editor.

Dr. William A. Dunn of Boston, Mass., has been honored by Pope Pius X, who has conferred upon him the order of knight commander of the Order of Gregory the Great.

Dr. William Henry Howell, professor of physiology and dean of the faculty of the Johns Hopkins Medical School, will deliver the anniversary lecture before the Yale Medical School at the commencement in June.

State Board of Examiners in Osteopathy.—The Legislature of Nebraska has recently passed a law providing for the establishment of a State board of examiners in osteopathy. The use of drugs in the treatment of patients by doctors of osteopathy is prohibited.

The International Medical Congress.—Dr. J. H. Musser writes that he has received a letter from the Secretary-General of the International Medical Congress, to the effect that authors of communications have time to send in their papers until May 15, and if they are not able to prepare them by that date, they may be presented at the time of the Congress, with the understanding that such communications will be published in the second volume of the Congress Reports.

The Alabama State Medical Association will hold its annual meeting in Birmingham on April 20.

The New London (Conn.) Medical Association held its 118th annual meeting at Norwich, on April 1. The following officers were elected for the ensuing year: *President,* Dr. George H. Jennings of Jewett City; *Vice-president,* Dr. Patrick J. Cassidy of Norwich; *Clerk,* Dr. Edward C. Chipman of New London; *Councillor,* Dr. Edward P. Brewer of Norwich; *Censor,* Dr. Charles F. Brayton of Stonington.

The Brown-Redwood (Minn.) Medical Society, at its annual meeting on March 31, at New Ulm,

elected the following officers: *President,* Dr. F. A. Gray of Vesta; *Vice-President,* Dr. J. L. Adams of Morgan; *Secretary and Treasurer,* W. A. Brand of Redwood Falls; *Censor for three years,* Dr. G. R. Pease of Redwood Falls; *Delegate to the State Meeting at Winona in June,* Dr. G. F. Reineke.

The St. Clair County (Mo.) Medical Society, at its annual meeting at Belleville, on April 1, elected the following officers for the ensuing year: *President,* Dr. W. S. Wiatt, East St. Louis; *Vice-President,* Dr. George Hilgard, Belleville; *Secretary,* Dr. E. W. Lane, Edgemont; *Treasurer,* Dr. Adolph Hansing, Belleville; *Delegate to State Medical Society,* Dr. A. B. Gunn, Belleville.

Dust and Consumption.—It is stated in a recent bulletin of the Bureau of Labor that 14.8 per cent. of all deaths of males over 15 years of age in the United States are from consumption. The percentage of deaths from this disease among men engaged in dusty occupations ranges from 24.8 per cent. for those exposed to vegetable fiber dust to 36.9 per cent. for those exposed to metallic dust. Those showing the highest consumption mortality are grinders, among whom 49.2 per cent. of all deaths are from that disease.

The Late Dr. Murray.—At a meeting of the Society of Alumni of Bellevue Hospital, held April 7, 1909, the following minute and resolutions were adopted: It becomes the painful duty of your Committee to record the death of our colleague, Dr. Robert A. Murray, on February 27, 1909. Robert Alexander Murray was born, of Scotch ancestry, in this city fifty-seven years ago last January. He took the degree of Bachelor of Sciences at the College of the City of New York in 1871 and that of Doctor of Medicine in the New York University Medical College in 1873, and in the same year became an interne in Bellevue Hospital, serving on the second medical division. He was Visiting Physician to the Northwestern Dispensary, diseases of women, 1876-1883; Visiting Physician to the Workhouse and Almshouse Hospitals, 1880-1884; Visiting Obstetrician to the Maternity Hospital, Blackwell's Island, 1884-1895; Assistant Professor of Obstetrics, New York University Medical College, 1876-1886. At the time of his death he was Associate Obstetrician to the French Hospital, and Assistant Visiting Surgeon to the Woman's Hospital. He was a member of the American Medical Association; the Congress of American Physicians and Surgeons; the American Gynecological Society, as well as many local medical societies. He had been President of the Obstetrical, Medico-Surgical, and Northwestern Medical and Surgical Societies, Chairman of the Section on Obstetrics of the Academy of Medicine, a vice-president and acting president of the County Medical Society, and at the time of his death he was President of the Society of Medical Jurisprudence for 1909.

As a regular attendant at our meetings the wide range of his professional experience gave dignity to his participation in discussion, while his happy disposition endeared him to all. Above all he belonged to the type of physician fast disappearing, the "family doctor," and as the "family doctor" he became a martyr to his conscientious regard for his professional duty. Stricken with pleuropneumonia he was fifteen hours later forcibly taken from the bedside of a toxemic woman to his home and to the bed from which he never arose. Thus he was faithful to the end, for saith the Divine Physician: "Greater love hath no man than this, that he lay down his life for his friend."

Your Committee also presents the following preamble and resolutions:

Whereas it has pleased Almighty God to remove from the sphere of his earthly usefulness our colleague, Dr. Robert Alexander Murray; therefore

Resolved, that we note our sincere sorrow for the great loss we have sustained, that we appreciate fully his genial and attractive personality and his high and conscientious character.

Resolved, that we extend to the members of his family our heartfelt sympathy and sincere condolences in this their hour of grief and sorrow.

Resolved, that this memorial, and this preamble and resolutions be spread in full upon the minutes of this society, that a copy be sent to each of the two local medical journals for publication, and to the family of our deceased colleague.

(Signed) Richard Kalish, Edward D. Fisher, Committee.

Obituary Notes.—Dr. Robert Crane of Waterbury, Conn., died at the home of his son, Dr. A. A. Crane, on March 31, aged 88 years. Dr. Crane was graduated from the Yale Medical School in the class of 1847, and had practised in New Haven for nearly thirty years.

Dr. Charles J. Leclair of Danielson, Conn., died on April 1, of pernicious anemia, after an illness of three months. He was a graduate of Victoria University, Class of 1887, and a member of the Connecticut State Medical Society and of the Windham County Medical Association, having been president of the latter for two years.

Dr. Andrew B. Gorham of Wilton, Conn., died at his home of heart disease on March 30, aged 58 years. Dr. Gorham was graduated from the Yale Medical School in 1879, and had practised continuously in Wilton for thirty years. He was a member of the Connecticut State Medical Society.

Dr. Robert Eleazer Ensign of Berlin, Conn., died suddenly at his home on March 30, aged 75 years. Dr. Ensign was graduated from the Albany Medical College in 1857. He was consulting physician to the New Britain Hospital, and a member of the Connecticut State Medical Society. During the Civil War he served in the Sixth Connecticut Regiment.

Dr. Hugh J. De Ver of Waterbury, Conn., died suddenly of apoplexy, on April 9, aged 60 years. Dr. De Ver was born in Ireland and was educated at the University of Dublin and the University of Glasgow, receiving his medical degree from the latter in 1875.

Dr. Harry Ogden Fairweather of Troy, N. Y., died on April 8, as the result of a fracture of the skull while he was fighting a fire a few days before. Dr. Fairweather was graduated from the Albany Medical College, in 1896, and was an attending physician to the Troy Hospital. He was a captain in the Hospital Corps Department of the Second Regiment, N. G. S. N. Y., and a member of the Association of Military Surgeons of the United States.

Dr. Luigi Galvani Doane of New York died on April 4 in the house in this city in which he was born fifty-nine years ago. Dr. Doane was graduated from the medical department of the University of Michigan in 1871, and practised in this city until failing health compelled his retirement some years ago.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

X-RAY CANCER—HUNTERIAN LECTURE—TREATMENT OF ASTHMA —CHARITIES' COMMISSION—AMBULANCE SERVICE—SLEEPING SICKNESS—SURGICAL CONVALESCENT HOSPITAL—OBITUARY.

London, March 26, 1909.

Professor Cecil W. Rowntree of the Middlesex Hospital cancer research laboratories delivered a Hunterian lecture at the Royal College of Surgeons on the 17th inst. on *x*-ray carcinoma and an experimental inquiry into the conditions which precede its onset. Of the eleven cases that have occurred in this country, there has been one malignant, an abstract of which would illustrate what may happen in all. This one shows what may happen in the absence of early surgical interference. When first operated on he had been working with the rays for some years and had had severe dermatitis. For eighteen months he had had a growth involving a whole finger, irregularly lobulated, ulcerating, very foul. Skin on back of hand thin, atrophic, and there were numbers of pigmented warts. No enlarged glands. Amputation was done through the proximal end of the metacarpal bone in 1905. The hands remained stationary for some time, but severe dermatitis developed on the chin and on the part of the chest where the waistcoat was open. Last month the patient came again, with growths on the other hand, the first finger having sloughed off, and the second and third involved. On the chin an extensive growth, apparently cancerous. The second and third fingers with corresponding metacarpal bones were removed. No operation on the chin at present. Microscopic section of the first growth shows that it infiltrated surrounding structures and invaded blood-vessels in the manner of malignant growths. The second growth on the opposite hand had nothing to distinguish it from squamous carcinoma. This has long been thought to be connected with chronic irritation and the question arises whether the *x*-rays may be so classed or have a special action disposing epithelium to malignant degeneration. On this Professor Rowntree drew attention to the fact that *x*-ray cases are multiple, other cases almost always single. The resemblance of *x*-ray dermatitis, he said, to xerodermia pigmentosa had been noticed from an early period, and this resemblance is the more striking from the cases of xerodermia in which carcinomata has supervened. The *x*-ray cancer is generally of a low degree of malignancy and therefore the lecturer considered it probable that, instead of amputation, simple excision of the growth might be safely carried out before the ordinary appearances of cancer have been attained. But microscopic examination might show that when the naked eye did not.

The lecturer next gave a description of the results obtained by exposing mice, rats, and rabbits to *x*-rays for various periods and then to the effects of the rays on a nonvital part of these animals—their tails and ears. Sections of the skin of rats' tails showed three distinct regions: (a) The ventral surface unaffected, (b) dorsal surface destructive change, (c) the sides hypertrophied. More striking still were the results on the ears of rabbits, which are thinner than the rats' tails, and penetration occurred on the unexposed surface, which was more hypertrophied than the sides of the rats' tails.

The effects differed from those of ordinary irritants in that the *x*-rays showed a selective action, and, further, they influenced nutrition long after the exposure Moreover, they had a distinctly stimulant action. Having compared these results with those of other observers, the lecturer said the stimulant action had scarcely received sufficient attention. To it we might ascribe the epithelial and wart formation produced by small doses, as seen in the hands of workers, for the coat and shirt sleeves would be poor protection against large doses and only extreme care could prevent the hands of workers getting small doses. But more than the stimulus of epithelial tissues may occur. Probably there were two essential conditions for the formation of a squamous carcinoma: (1) The presence of a mass of cells capable of multiphiature; (2) a surrounding area of connective tissue in such a condition as to be vulnerable to epithelial invasion. These conditions seemed to obtain.

In regard to treating cancer with *x*-rays, all observers agree that it is only in very superficial conditions that amelioration can be expected. Of all malignant growths rodent cancer is most superficial. Only in that have good results been seen, and even in that discordant. In some the tumor disappeared after two or three exposures, in others healing and breaking out again, in others not healing at all. Possibly in some the dose has been too large and something like an *x*-ray burn produced; in others perhaps the dose was just enough to induce the retrogression of the superficial parts, while in the deeper parts it stimulated to greater activity.

The Therapeutical Section (Royal Medical Society) has held a discussion on "The Treatment of Spasmodic Asthma." It was opened by Dr. R. C. B. Wall, who remarked on the part which theory played in suggesting remedies, though it had produced little agreement, except in the opinion that during an attack there was diminished calibre of the bronchial tubes, and this probably through some influence on the central nervous system. But he acknowledged that the work of Brodie and Dixon supported the hypothesis of muscular spasm. Professor Dixon, who was present, subsequently showed tracings indicating diminished volume of the lungs, produced by stimulating the organs of a cat, and said a like result followed reflexly stimulation of nasal mucous membrane. The professor further illustrated the action of drugs which inhibited spasm, and said to produce asthmatic attacks two things were necessary—a neurotic inedulla and a peripheral stimulus. To return to Dr. Wall's paper, he said prophylaxis attempted to hinder the passage of nervous impulses to the lungs or prevent their origin in the center. Symptomatic treatment was directed toward widening the bronchioles, as by removing turgescence of their lining, or to relaxing the tone of their muscles. Environment as to temperature and climate was to be considered. He observed nasal defects in twenty-three cases; in fourteen of these treatment directed to this had been followed by great improvement, but in not one by a cure. Of drugs, he found potassium iodide, arsenic, and stramoniam most useful. Of the last he preferred the extract in smaller doses than the B. P. named. Toxic symptoms often occurred with three-quarters of a grain in twenty-four hours. Morphia was valuable, but there was danger of its leading to narcomania. Nitrites, atropine, and other drugs were useful in some cases.

Dr. A. F. Hertz, from personal experience, said the determined exercise of the will would sometimes prevent an attack. He had diminished one by resolute persistence in mental work. If a patient expected an attack it would come. Asthmatics should avoid places where they had had them. Dr. Spriggs had notes of forty cases and said patients who were quite free between attacks were hopeful, but those which only subsided into a chronic dyspneic state were very difficult. He had seen strict attention to diet and regimen give excellent results. Nasal treatment might do good or the reverse. In one case a series of most severe attacks were set up by removal of a polypus. He had had good results from injecting 1/100 of a grain of atropine and repeating in an hour if necessary. He uses this and amyl nitrite most often, except perhaps chloroform and morphia. If amyl produced relief, the patient should keep quiet and if possible sleep; on waking the worst would be over. Dr. Carmalt-Jones said that working in Sir A. Wright's laboratory he had isolated an organism and had prepared a serum which allayed dyspnea. Dr. Duncanson strongly recommended breathing exercises, especially in young patients.

The report of the Charity Commissioners was issued as a bluebook on Wednesday. It contains a record of unreported and new charities and returns of accounts of charitable institutions, trusts, etc. In reference to old-age pensions, questions of great importance have been raised and the advice of the commissioners sought. Trustees of charities wishing to benefit the largest number of people in need have sometimes desired to reduce the stipends of their pensioners and almspeople who have become entitled to the old-age pensions and apply the money saved to assist further persons in need.

The report of the committee on the ambulance service appointed by the Home Secretary states that the present system is greatly defective. They do not like the wheeled litter and would welcome the supersession by a rapid ambulance of all other modes of conveyance. They think the system organized by the asylums board for infectious cases might well be adopted for accidents and noninfectious cases. Small stations

should be established throughout the metropolis at which rapid ambulances, preferably motor, should be kept, and if possible a police officer trained for first aid who could accompany it in most cases. As to dealing with cases on the spot, whether accident or sudden illness, the report quotes the evidence of Sir Wm. Church that the experience of St. Bartholomew's Hospital was that the "first aid administered by the city police is excellent." Though that of the metropolitan force was not quite equal, "it was not bad," and with practice and help no doubt would rapidly improve. This the committee think would fit them for the new responsibilities proposed to place on them.

From the ninth report of the Royal Society's commission on sleeping sickness a further note may interest you. I have previously mentioned the importance of the fact that the regions where the tsetse is found are more restricted than was supposed and that success has attended the compulsory removal of the inhabitants to other localities. But then the habits of the natives render it so difficult to isolate any part as to render prevention almost impracticable. In order to secure the cooperation of the natives it is necessary to supply them with information and the assurance that there is no reason for their fatalism. For this purpose an address has been prepared in the native languages, the circulation of which among the more educated may bring about their cooperation, without which the task of exterminating the disease seems hopeless. Some of the chiefs have been impressed and have assisted somewhat in the removals from infected districts which have already been carried out. With compensation for the losses incurred, the natives will learn that their good is intended.

The project to establish a hospital in the country for surgical convalescents discharged from London hospitals is supported by many leading surgeons and is pretty certain to be carried out, as it is interesting the royal family and approved by the King. A trust deed has been adopted which binds the promoters not to purchase a house or site until they have in hand a sum producing from £900 to £1,200 a year to set the institution going. It is thought that many patients may be sent out earlier to such a hospital, where their unhealed wounds can be dressed with skill and they will have the advantage of fresh air.

The death is announced of Dr. James Hamilton Stirling, the eminent writer on philosophical subjects, who was educated for the profession and in early life held appointments as surgeon to iron and coal works in South Wales. He was a Glasgow citizen, born there in 1820, and studied at the university and afterward in France and Germany. In 1851 he gave up medical practice and devoted himself to literature and philosophy. In 1888 he was Gifford lecturer at the Edinburgh University, by which as well as by that of Glasgow he was made LL.D. Among his works may be mentioned the "Text-Book to Kant," the "Secret of Hegel," "Of Philosophy in the Poets," and his work on Hamilton and the philosophy of perception.

News has been received from India of the death at Cawnpore of Major J. S. Edye, R.A.M.C., at the early age of 45. He had served in the South African war, receiving the Queen's Medal with four clasps.

Deputy Surgeon-General Richard Hungerford died on the 19th of March in his seventy-fifth year. He took part in the Crimean campaign and was present at the siege of Sebastopol, receiving the medal and clasp as well as the Turkish Medal. Afterward he served through the Indian mutiny, being present at the storming of Mecangunge and the siege and capture of Lucknow, and received the medal with clasp for the campaign.

Dr. Charles Coates, F.R.C.P., of Bath died on Tuesday at the age of 83. He graduated M.D. at Edinburgh in 1857. He was consulting physician to the Royal United Hospital and had been long on the staff of the Mineral Water Hospital at Bath.

(From Our Regular Correspondent.)

THE MODE OF ACTION OF FULGURATION ON CANCEROUS TUMORS —THE LUYS PROCTOSCOPE—HUMAN OVARIAN GRAFTS—HOT AIR IN THE TREATMENT OF DIABETIC GANGRENE.

PARIS, March 25, 1909.

THE mode of action of fulguration upon cancerous tumors has been studied by Zimmern. Among the phenomena observed after fulguration of malignant tumors by the Keating-Hart method, one especially strikes the attention. This is the remarkable activity of the process of repair, the rapidity of closure, and the perfection of the cicatrix. The repair of the primary cancer tissue comes about by the production of abundant fibrous tissue. At the bottom of the fulgurated wound appears, first, after the fall of the eschar, supple, elastic granulation of a rose color. At the same time there occurs a reconstruction, a rapid centripetal development, which indicates a true reaction of the connective tissue under the influence of the current. To sum it up, the current of high frequency has the remarkable property of powerfully exciting the process of fibrosis. The current is essentially a precious auxiliary in surgery in torpid and malignant wounds. Since it increases the chances of rapid cicatrization, it permits of extended operations which formerly were impossible.

Pozzi also has observed the considerable cicatrizing power of fulguration. He advises the use of fulguration in two cases: First, when it is possible to remove the tumor entire; second, when a complete operation is impossible. In cases of small, easily removable tumors which allow of an operation extending well beyond their limits extirpation is preferable.

Pierre Fredet, in an interesting article on this subject, shows that we cannot as yet say that fulguration will cure cancer. It is only a palliative method, but one which is of great utility. For the present the best treatment for cancer continues to be broad and early extirpation. An early diagnosis, no hesitation, and no half-measures is the formula of the hour.

At a recent meeting of the Surgical Society Pierre Delbet presented a new proctoscope designed by Luys, which differs essentially from other similar instruments in that it is furnished in its interior with a special tube, fastened to one of its walls, which terminates at the external end of the instrument by an adjustment to which can be attached a rubber tube, which itself may be attached to an aspirating apparatus. The light is obtained from a minute electric lamp mounted on a long stem, which lights the interior extremity of the proctoscope. The great advantage of this instrument is that fecal matter never obstructs the view. If the feces are liquid they may be aspirated by the water tube; if they are semi-solid a jet of water is thrown in and aspiration then removes the feces softened by the water. Everyone who has practised proctoscopy knows how much the examination can be delayed by the presence of feces, and how slow and difficult it is to remove them with tampons manipulated at the end of long forceps. The changes made in this instrument are such as to render true service to the operator.

Quénu and Sauvé have recently recalled the importance of the internal ovarian secretion. It has a double rôle: A genital action, which begins with the fecundation of the ovule, and a general action, which appears to be synergic to the thyroid secretion, and the suppression of which causes the production artificially of the troubles which generally characterize the menopause. The preservation of the ovaries should be attempted whenever, in the course of a surgical operation, the surgeon finds himself obliged to remove the patient's ovaries by attempting to graft the removed ovary upon an appropriate site. Quénu has observed a human ovarian graft made ten months before in a woman of twenty-five years, who had undergone a bilateral castration for salpingitis. The ovarian graft was made on the skin of the abdomen, but it had not prevented the patient from suffering all the symptoms of ovarian insufficiency. On removing the grafted ovary Quénu found by histological examination that the mass taken away was formed entirely of connective and adipose tissues, with no trace of interstitial cells. The tissue of the ovary was completely degenerated. Mauclaire has attempted to graft ovaries subcutaneously at least twenty times. The results obtained have not been very encouraging. He believes that if the results are so often negative it is because the ovaries are insufficiently vascularized. Tuffier has made forty-seven ovarian grafts. In his early grafts he implanted the ovary between the folds of the broad ligament, but soon abandoned this procedure in favor of subcutaneous grafts. He found that when the graft took it always remained somewhat sensitive to pressure. Some patients had noticed at times a swelling of the graft without redness, sometimes reaching the size of a mandarin, but without any periodicity similar to menstruation. Menstruation never reappeared

and all the patients experienced the habitual troubles of the operative menopause.

Ricard presented at the same meeting five patients attacked by diabetic gangrene, who had been treated by hot air and cured. This is not a true cure, but an arrest of the evolution of the gangrene, for, properly speaking, there is no cure for gangrene; all the dead tissue is truly dead, and we know no way of giving life again to a tissue that has ceased to live. In the treatment of diabetic gangrene two things are necessary: First, the dead tissues are dried and carbonized; second, an active hyperemia is produced by projecting on the edges of the healthy tissues a douche of hot air at 60°-80° C. (140°-176° F.). We then see the tissues swell, grow red, granulations appear, the eschars are separated, and the process of cicatrization begins.

Delbet believes that infection plays an important rôle in the production of diabetic gangrene. This begins with lymphangitis, which easily becomes gangrenous in the sugar-containing tissues. Hot air acts especially by its antiseptic qualities. It arrests the gangrene by arresting the infection. Tuffier believes that superheated air between 50° and 120° C. (122° and 248° F.) finds its application as a treatment for diabetic gangrene from (1) the caustic action of the hot air douche, an excitant which stimulates cicatrization very rapidly; (2) as the bath of superheated air. It causes a hyperactivity throughout all the superheated zone, which diminishes the chances of invasion of the tissues by gangrene and helps cicatrization.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

MEETING OF THE PHILIPPINE ISLANDS MEDICAL ASSOCIATION.—REACTION OF CULTURE MEDIA IN RELATION TO THE MORPHOLOGY OF THE CHOLERA ORGANISM—CLINICAL FEATURES OF TROPICAL DISEASES—ACCOUNT OF THE TUBERCULOSIS CONGRESS—BACTERIAL VACCINATIONS—BERIBERI.

MANILA, P. I., February 26, 1909.

The fifth annual meeting of the Philippine Islands Medical Association took place in the Philippine Medical School Building, and the first session was held at 4 P.M., February 10. Addresses were made by His Excellency, the Governor General, and by the president of the association. The latter dwelt particularly upon the importance of the question of tuberculosis in the Philippine Islands.

The first scientific session was begun at 10 A.M., February 11. Papers were read by Dr. Henry E. Ruediger, entitled "Filtration Experiments on the Virus of Rinderpest with Chamberland Filter 'F,'" and by Dr. Y. K. Ohno, entitled "The Reaction of Culture Media in Relation to the Morphology of the Cholera Organism." In view of the constant presence of cholera in the Philippine Islands, this latter paper was of considerable interest, especially as the author has apparently shown that the form of the cholera organism can be varied, depending upon the class of media upon which it is grown. For instance, in peptone solutions of acid reaction the vibrios lose their spiral character and form a rod, while in strong alkaline media they shorten and appear as ovals or even spheroids. These observations were made with strains which had been kept in the laboratory for some time. In the dejecta of cholera patients which came to the laboratory for examination, the differences in form of the cholera organisms noted above were also found, depending upon the reaction of the stool. Dr. Ohno stated that at this time he was not prepared to report upon the character of the cholera vibrio found in vibrio carriers, but that his observations to date show that of seven vibrio carriers, in five of them the serum agglutinated the strain moderately, while two others had very low agglutinative value without showing any symptoms of the disease at a later date. From this result he concludes that there must be a local immunity in the intestinal wall which is different from the humoral immunity of Wassermann and Citron.

The next paper, by Dr. Thomas W. Jackson, Medical Reserve Corps, U. S. A., entitled "Some Clinical Features of Tropical Diseases," consisted of brief notes of the tropical diseases which he had encountered in his tour of service in the Philippines, and invited particular attention to the fact that he had not found ipecac to be either a specific or as valuable as many writers reported it to be in the treatment of amebic dysentery, and also that of the many theories advanced with regard to the origin of beriberi, he was unable to confirm any of them from his own observation.

The next paper, by Dr. Victor G. Heiser, Director of Health, entitled "The Third International Congress on Tuberculosis," gave a brief description of the congress, and laid particular stress upon the unanimity of opinion that existed throughout the civilized world with regard to the measures of a general public character which should be taken in order to grapple with the tuberculosis problem most successfully.

The next paper, by Dr. Eugene R. Whitmore, Captain, Medical Corps, U. S. A., entitled "Further Observation on Bacterial Vaccinations," is a continuation of the line of work which the author reported at the last annual meeting. His experience with opsonins has been satisfactory, especially in the treatment of gonorrheal cases. Otherwise, his experiences have practically been the same as those of other writers upon this subject.

There were four more scientific sessions held, at which the following papers, among others, were read: "The Nastin Treatment of Leprosy," by Dr. Oscar Teague, was negative in character, no results having been obtained after three months' trial of this method.

"Observations upon an Epidemic of Beriberi," by Dr. Louis Brechemin, Jr., Captain, Medical Corps, U. S. A. This paper brought forth nothing new with regard to beriberi, but produced a most lively discussion in which many of the members of the association took part. Considerable evidence was deduced that the disease is due to infection, and the probabilities are that it was conveyed by insects. Other speakers showed that in the outbreaks which had occurred recently in the Phillipine Islands the measures which have once been used successfully in the stamping out of the disease in a few weeks' time failed utterly a year later, and so it is questionable whether the measures which were formerly adopted had any real effect in limiting the number of cases. The discussions showed clearly that, although most of those who took part in them were physicians who have had large experience with beriberi, yet the data which they had collected was at best very contradictory, and nothing definite with regard to the origin of the disease can be deduced from it at the present time.

MEDICAL UNION.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Some time ago I saw in a publication authorized by the American Institute of Homeopathy that the whole number of homeopathic graduates in the United States for the year 1908 was 243. The statement came in the nature of a surprise, when it is recalled that a few years ago such graduates were turned out annually by the hundreds. Pursuing my investigations further, I find in studying the various announcements of the seventeen American homeopathic colleges that, accepting their own account of things, the end of that branch of sectarian medicine cannot be far off. It is dying at both the top and the bottom.

I do not write this to give offence to sectarian practitioners, for many of whom I entertain nothing but the warmest sentiments of respect, but what does the record show? The State University of the rich and progressive State of Iowa can muster only forty-three matriculates in its homeopathic department, an average of fewer than a dozen to each class. The University of Michigan, with its great local and foreign prestige, has seventy students in all four classes. One of the oldest homeopathic colleges has a faculty of thirty-six and a graduating class of one. It is gravely announced in black face type that "our classes are not so large but that we can take a personal interest in each and every student." As the whole number of matriculates was seventeen, it will be seen that, with a faculty numbering thirty-six, this statement is literally true. Another old college, with a large and able faculty, has far fewer in the classes than in the faculty. One college has a faculty of forty-six and a graduating class of sixteen. It publishes no list of its matriculates, whether from fear of criticism or from lack of resources is not stated. Another institution, with a graduating class of fifteen, has a faculty numbering about fifty. One of the oldest, strongest, and best equipped homeopathic colleges has a faculty of nearly a hundred and a graduating class of fewer than fifty. Its list of matriculates has diminished to about the same number as the faculty. It is as clear as anything can be in the future that further division in the ranks of the medical professional is not sustained by public opinion. A united profession is in sight.

Candid homeopathic physicians admit in private that the end of "organized" homeopathy is at hand, yet they

express some resentment at having to "surrender" something that appeals to them, from force of training, perhaps, as a principle to which they claim to be devoted.

May I not, in all kindness and candor, ask of the objectors some pertinent questions?

Who has asked you to give up any principle which your conscience and experience tell you is desirable?

Has any one asked you, much less required you, to practise his way, or to give up anything that you believe to be for the best interest of your patient?

You accuse us of stealing your thunder and of unconsciously practising your principles without giving you credit, but when have we ever objected to your appropriating our thunder or making the freest use of our methods, which we have never claimed as ours exclusively, but as belonging to all practitioners of our art? You charge us with not associating with you. Are you willing to keep company with us? If some of your methods are better than ours, is it not your bounden duty to seek us out and try to show us a better way? Granted that some —say all—of your therapeutic claims are true, is an honest therapeutic difference sufficient to divide the medical profession into hostile camps?

In conclusion, I hope that the regular profession the country over will make a determined and systematic effort to set the real facts before scattered sectarians, to the end that all may be brought within the fold of progressive medicine. I do not believe that many of them will require much urging. Certainly I do not believe that any regular practitioner is to be harmed by contact with any one outside the fold. MEDICUS.

POSTURAL DULLNESS AND AN EXPLANATION OF GROCCO'S SIGN.

To the Editor of the Medical Record:

SIR:—I have read the article of Dr. Albert Abrams in your issue of April 3, and wish to call attention to the fact that the postural dullness he attributes to a passive hyperemia can just as well be explained by temporary atelectasis on the side compressed (side on which patient is inclined or lies), this causing a corresponding emphysema on the opposite side of the chest by virtue of the increased air pressure at this site. This accounts for the hyperresonance which Dr. Abrams noticed but did not explain. Speaking of Grocco's sign he mentions having found it in normal lungs, attributing it to passive hyperemia, and making the dullness disappear by placing the patient in the prone position.

Another good explanation for this phenomenon, I think, is the following: Dr. Krönig demonstrated in cadavers that the healthy lung does not extend all the way down at the side of the vertebræ posteriorly, but deviates to the side in the lower portion, here leaving a triangular space without lung, and so accounting for the paravertebral triangular dullness. Now, if a patient be placed in the prone position the increased air pressure will fill out the lung posteriorly and extend the lung into this triangular space, and so obliterate the dullness.

JAMESBERG, N. J. JULIUS KAUNITZ, M.D.

THE INTRABDOMINAL USE OF OXYGEN.

To the Editor of the Medical Record:

SIR:—Your editorial on "Intrabdominal Use of Oxygen," in the April 3 issue of the Medical Record, prompts me to call your attention to two papers published by me in *American Medicine*, March 22, 1902,[1] and November 8, 1902,[2] on the oxygen bath for the peritoneum. In an advanced case of cancer of the breast, associated with great pain and dyspnea, I was enabled to give great relief by pumping the abdomen full of oxygen. The effect of this remedy was very striking, the infiltrated tissues, the bad heart action, the engorged lungs, and dyspnea all disappeared as if by magic. The action of the remedy seemed to depend upon a stimulation of the lymphatics, starting from a stimulation primarily in the peritoneum.

The thought occurred to me at the time that this oxygen bath would prove beneficial in tuberculosis of the peritoneum. I thought, too, of tuberculosis of cattle and the frequent involvement of the peritoneum in the general tuberculosis of these animals. I suggested this remedy to Professor V. A. Moore, of Cornell University, and he tried the experiment with infected cattle simply by pumping up the abdomen with an ordinary bicycle pump. This treatment seemed unavailing. Some died suddenly from the operation; with the others there was no improvement. I still believe that with more carefully conducted experiments we may learn something of the value of the remedy in tuberculosis conditions. The thought has also come to me that in a disease like pneumonia, a general infection with a local manifestation in the lung, this stimulation of the peritoneum and the lymphatics may prove of great value. I am not aware that the use of oxygen by inhalation has ever been anything else than a temporary relief in pneumonia, but I do think that its intrabdominal use does give some promise of a curative action in those cases which are grave and menacing. Unfortunately, I have had no opportunity myself to test this treatment, but I can see no danger from the procedure when properly done.

I was glad to see Dr. Bainbridge's article in the *Annals of Surgery*, and I hope the subject will come to the attention of the profession generally, and that the procedure will be thoroughly tested. EUGENE R. CORSON, M. D.

11 JONES STREET, EAST, SAVANNAH, GA.

1. A Simple Exploratory Laparotomy as a Palliative, and Perhaps Curative, Measure in Inoperable Carcinoma of the Breast; Preliminary Report of a Case.

2. The Oxygen Bath for the Peritoneum and Its Possible Value.—Second Report on the Cancer Case Relieved by an Exploratory Laparotomy.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 1, 1909.

The Wassermann Reaction in Syphilis and Other Diseases.—R. L. Lee and W. Whittimore say that a positive serum reaction for syphilis is obtained in 89 per cent. of all cases of syphilis of whatever stage. In the active secondary and tertiary stage a positive reaction is obtained in 95 to 100 per cent. Known normal cases apparently give invariably a negative reaction. Some chronic diseases accompanied by marked emaciation near death may give positive reactions. This seems especially true of tuberculous cases, but under such circumstances there is usually no question of a differential diagnosis of syphilis. In other diseases the reactions are generally negative. The few positive reactions might well be explained by the possibility of the incidence of a latent syphilis. The authors prefix their conclusions with a description of their technical methods, which they claim to be somewhat simpler than that of Wassermann.

Recent Progress in the Treatment of Various Conditions Called Rheumatism.—R. B. Osgood opens his paper with a reference to the joint conditions produced by lactic acid, uric acid, infections, etc., all of which have been loosely called rheumatism. He comments on the wide use of salicin and its derivatives, and says that there are still grounds for questioning the specific action of salicylic acid except as a reliever of pain. The authors refer to serum therapy, but note the difficulty of knowing what serum to use. This is still an open question. Reference is also made to the hot bath plan of Schweninger and the Bier treatment. Palliative measures are referred to, and the author notes the tendency of recent years to regard acute rheumatic fever as an infection in which we have come to place much less reliance on drugs and far more on those measures calculated to combat the infection, and conserve those natural forces within the body where protective activities are called forth by the appropriate disturbance. The subject of infectious arthritis is led to a consideration of its causes and the destruction of the foci of infection. No drug is of any special service, though guaracol carbonate and the salicyl group will relieve the pain. We can do much by orthopedic apparatus to prevent deformity and subsequent disability. A detailed reference is made to various affections of the bursæ and other periarthrodial structures commonly considered rheumatic, but now recognized and referred to their proper respective structures.

New York Medical Journal, April 3, 1909.

Nature and Treatment of Neurasthenia.—S. T. Rucker says that experience has taught him to regard neurasthenia as a serious malady and one that is difficult to treat. The mistake is sometimes made of advising a patient who is in a state of nervous exhaustion to travel. The irritating annoyances incident to long journeys are well known to those who have traveled much. Many people who enjoy good health are fatigued by travel; the neurasthenia patient craves for complete rest and quiet. Travel, especially a sea voyage, is often beneficial after the patient

is convalescent. An occasional tour of sight seeing is also advisable to the neurasthenic business and professional man, but it is before a nervous breakdown occurs. The keynote to the treatment of neurasthenia is rest in bed, augmented by diet, hygiene, medicines, and suggestion. In this way the expenditure of energy is reduced to a minimum, lost strength is regained, and impaired function is corrected. Women respond more favorably to the complete rest cure than men. Separation from the environments of home and strictly excluding the injurious influences of relatives and friends, are large factors in treatment. The author then enumerates the remedies and therapeutic devices he has found of service.

Two Unusual Cases of Typhoid Fever.—The report is given by F. W. White, whose first case was that of a child of eleven years, in whom, about the tenth day of a moderately severe fever, then developed a parotid bubo, followed four days later by a consolidation of the base of the left lung posteriorly. The pus from the parotid contained staphylococci, but no pneumococci, though the latter were present in the expectoration. Patient recovered. The author's second case—fatal—was that of a woman of nineteen years, in whom at the end of the second week there occurred a severe nosebleed, easily controlled. This reappeared in a few hours and recurred at intervals within the next few days, and finally became uncontrollable. There was finally a large intestinal hemorrhage, but none from the gums, nor were there any hematuria or hemorrhagic manifestations in the skin. There was no autopsy. The girl had been subject to nosebleed, but not to other spontaneous hemorrhages. There was no history of hemaphilia.

Exophthalmic Goiter.—C. A. McWilliams gives a general description of this condition and summarizes the statistics of recent surgical intervention. In the author's opinion, nearly all the cases deserve treatment with the Rogers and Beebe antiserum before operation is advised. The object of this antiserum is to bring about destructive changes in the hypertrophied thyroid by a process of cytolysis. The nucleoproteids and globulins from the human gland are injected into sheep and hares and from these animals is obtained the antiserum for use in human beings. Osler gives a case three months of medical treatment before advising surgery. The surgical technics are described by the author, who notes that the surgeon's problem is to decrease the secreting power of the gland to a point where the bodily functions are brought to a normal activity. We may cut off the blood supply to the gland or remove more or less of the gland itself. One case is cited in detail and illustrates many of the points referred to by the author.

Journal of the American Medical Association, April 3, 1909.

Sanitation of the Tropics.—W. C. Gorgas gives a history of the eradication of yellow fever in Havana and Panama and describes what he would consider a model organization for this purpose in a tropical city. The stegomyia, the mosquito which transmits yellow fever, breeds principally around the dwellings of man, and the chief work of sanitation will have to be through the municipal sanitary organizations. The first step would be to have a correct system of accounts, but not too cumbersome. The next step is to get the authority to enforce the sanitary measures and to control their enforcement at every stage, fining the mosquito breeders, and power for the health official to abate the nuisance with his own force when the property owner will not do it, the cost to be made a lien against the property. This is a very important measure. A third ordinance should be passed for screening gutters, wells, cisterns, etc., so that mosquitoes cannot breed in them. He would also have a thorough system of inspection, and with these measures he holds that all that is necessary for yellow fever prophylaxis is accomplished. He gives an estimate of the cost of such an organization for a population of about 3,000 people, amounting to $1,900, and for 30,000 to only $5,000. In addition, the care of the sick should be looked after, and when a case occurs the patient should be promptly isolated and guarded to prevent infection of others. The same measures will be effective against malaria. The deaths from malaria prior to 1896 in Havana averaged about 250 per annum. This has fallen within the last year or two to less than fifty a year, and these, Gorgas believes, do not originate there, but are the natural incomers from the rest of the island. In a city situated like Havana this means the extinction of malaria. Concerted action in the various countries, he believes, would extinguish these diseases at once and without undue labor.

Aural Diagnosis.—G. E. Shambaugh describes the anatomy and physiology of the auricular apparatus and the methods of examining it for diagnostic purposes. He lays down the following propositions as established: "First, if the semicircular canals are normal and the ear is syringed with cold water, vertigo will result and there will be set up a nystagmus increased by directing the eyes toward the opposite side. If the ear is syringed with warm water the same symptoms will occur, but the nystagmus will be toward the same side. Second, should there exist an irritation of the endings of the vestibular nerve in the labyrinth, such as may be occasioned by a circumscribed suppuration in the labyrinth, there will be spontaneous nystagmus directed toward the same side. Syringing the ear with cold water will produce a positive reaction. Third, if there occurs a sudden destruction of endings of the vestibular nerve, such as would be occasioned by a diffuse suppuration in the labyrinth, there will be set up a spontaneous nystagmus directed toward the opposite side, but lasting only from a few days to several weeks. This nystagmus has its origin in the opposite normal ear. Syringing the affected ear with hot and cold water produces no response. Fourth, in case of long-standing destruction of the nerve endings in the vestibular nerve, such as occurs in chronic diffuse labyrinth suppuration, there will be no spontaneous nystagmus and no reaction can be obtained by syringing the ear with hot or cold water. Fifth, in case of cerebellar disease, such as cerebellar tumor, cerebellar abscess or a meningitis in this locality, there will occur a spontaneous nystagmus directed toward the affected side." Hence with pronounced rotating nystagmus and normal tympanum the presence of a cerebellar tumor may be suspected. On the other hand, the rotating nystagmus in a case of suppurative otitis media without fever but with severe deafness and nystagmus toward the affected side, while the syringing with cold water produces no response, suggests a cerebellar abscess. The complete destruction of the hearing in the affected ear would indicate a probable diffuse suppuration of the labyrinth. The failure to get caloric response on syringing points to destruction of end organs in the semi-circular canals. The only spontaneous nystagmus caused by this would be directed toward the opposite side. The lack of rise of temperature in most cases would exclude a meningitis, while a cerebellar abscess pressing on the vestibular nerve would produce a spontaneous rotating nystagmus which would be increased by directing the eyes to the opposite side.

Intestinal Localization.—G. H. Monks describes the mesentery and its characteristics, with those of the intestines, in different portions of the bowel. The characteristics of the loop of bowels in the upper portion of the intestine and of the mesentery attached to it, are the thickness of the walls, the large caliber, and the great vascularity, together with the numerous valves which can be easily felt through the walls. The attached mesentery, if there is not too much fat in it, exhibits large, long, straight vessels radiating to the intestine from arches (principally primary) deep in the mesentery. Ordinarily the mesentery is liable to be thin and to show the vessels. On the other hand, the characteristics of a loop of bowel near the lower end of the small intestine and of the attached mesentery are its thinness, small caliber, moderate vascularity, and lack of valves felt through the walls. The attached mesentery has relatively short, small, tortuous vessels, which spring from secondary or even tertiary loops deep in the mesentery. There is usually also more fat in this part. The transition between the two is gradual, but the surgeon can approximate the localization. Monks illustrates the situation in a general way by a cut in which the part over the first horizontal line lodges the uppermost third of the small intestine. If the incision is in the upper part of the abdomen, especially in the middle line or to the left of it, any loop of small intestine the surgeon meets will belong probably to the uppermost third of the gut; if his incision is in the middle part of the abdomen or in the left iliac, the loops belong probably to the middle third, and finally, if his incision is in the right iliac fossa or to the right of the rectus muscle, or even in the middle line between umbilicus and pubes, the loops will probably belong to the lowest third of the intestine. Monk describes a method by which in cases in which the abdominal wound is large enough to palpate the mesenteric root we can learn the right direction of the bowel. The loop is drawn well out of the wound, and its two extremities held upward by the assistant, the axis of the loop being kept by him parallel to the known axis of the root of the mesentery. The

surgeon's right hand is now applied to the loop in such a manner that his thumb is one side of the mesentery and his first two fingers are on the other. The thumb and fingers are then gently pushed downward in the direction of the root of the mesentery. If, by palpation of the mesentery, the surgeon detects no twist in it, he at once knows that the upper end of the loop (as it is then held) will, if followed up, conduct him to the duodenum, and that the lower end will conduct him to the ileocecal valve. If, however, there is a twist in the mesentery, the surgeon should withdraw his hand, remove the twist by turning the bowel, and examine again. When, finally, no twist remains in the mesentery, the surgeon knows that the end of the loop which is uppermost is the one which leads to the duodenum, and that which is lowest to the ileocecal valve. He describes also the procedure for protecting the intestines, when exposed outside the abdomen, by sheets of rubber, thus allowing the abdominal cavity to be more thoroughly inspected. In fact, the intestine and mesentery, including the whole small intestine, can be demonstrated by holding them on a rod above the abdomen. Also the intubation of the intestines for the purpose of emptying them can be effected best by the tube being introduced into the intestines through a small opening and not thrust into it, but having the intestine drawn over it as is done in the demonstration with the rod. The base of the pelvic fold of the mesentery forms an important landmark in the lower abdomen, that is, the lowest fold of the mesentery, and this is an important point in irrigating the abdomen, finding perforating ulcer, etc. It can usually be palpated through a wound in the lower abdomen, and the great fossa on the left of the abdomen may be reached by carrying the tip of an irrigating nozzle well around the pelvic fold and then pushing it upward. The lowest coil of the ileum can be picked up at once between the surgeon's thumb and finger by causing them to grasp the base of the pelvic fold of the mesentery and the loop of the bowel which is attached to it.

The Repair of the Internal Ring in Oblique Inguinal Hernia.—F. G. Connell emphasizes the importance of restoring the normal anatomic relations in the repair of oblique internal hernia, and points out the merits of the Ferguson operation, together with an elevation of the internal ring in preventing recurrence of the condition. The points he specially makes are, the suture of the transversalis beneath the cord, which causes minimization of the ring and the attachment of the internal oblique muscle to the other two-thirds of Poupart's ligament so that it covers and protects the internal ring. These measures result in a valve-like formation of the inguinal canal, which is important in preventing recurrence. They should be preceded by the removal of the sac at its neck with the redundant parietal peritoneum, and followed by the reunion of the divided external oblique aponeurosis and the formation of a suitable external ring. The article is illustrated.

Mild Atypical Typhoid Fever.—J. P. Bates reviews and analyzes sixty-three cases of mild typhoid, in a number of which a study of blood cultures was made. The analysis shows that over 32 per cent. of the cases were atypical, being resistant to quinin and too long in their course for malaria, while still too mild and short in their duration to meet the requirements of typical typhoid fever. There was a positive Widal reaction in all the cases included in this percentage, and the paracolon or typhoid bacilli were present in fully 24 per cent. A number of cases are reported, and the study shows that, instead of malaria similating typhoid, it is mild typhoid fever which similates severe malaria. At least this is the case in Panama, where the observations were made, and F. H. Harris has shown that the same forms occur in the southern United States. If the patient is put to bed and kept on rigid typhoid diet, the fever will subside in a few weeks or less. It is evident, also, what part such patients play in the spread of typhoid, as many of them will be bacillus carriers, and through them we will have a perennial source of the disease unless they are recognized and attended to.

The Lancet, March 27, 1909.

A Case of Retained Ovum.—J. L. Stretton notes the occurrence in a woman of fifty-four years operated on for a strangulated femoral hernia of a large procidentia of the uterus. It was decided to relieve the latter condition, the hernia having been attended to, and to ventrifix the uterus. At the operation for the latter a large strong lump was found in the left broad ligament and was removed. Recovery was uneventful. The lump consisted of a globular mass 5x3 inches, of smooth surface and stony hardness. On sawing it through it was found to contain a well-formed female fetus of about four and a half months. It was in perfect preservation and all the internal organs were easily made out. The envelope was everywhere invaded by calcerous deposit. The patient had been married thirty-two years. She had had two children in the first three years and two miscarriages later, but could not remember the exact date. The first of these was a formed child, the last consisted of blood and clots. At the second she was not attended by a physician, but was in bed for a week. It was certainly twenty years previously, which was probably about the date of the ovum.

Direct Esophagoscopy: An Unique Experience.—H. Tilley was called to see a baby four days old who had swallowed the teat of a "comforter." Symptoms indicated that it was lodged somewhere in the esophagus. Under chloroform the smallest bronchoscope of the Brünings outfit was passed into the gullet and when nearing the cardiac end (probably the phremic constriction) a white pulteous mass was seen and easily removed. It proved to be some cotton with which the teat had been stuffed. A second attempt removed the teat also. In a few hours the child was nursing in a normal manner. The author comments on the satisfaction afforded by direct vision in such cases as compared with the uncertainty of the old methods of allowing the foreign body to work its way or be pushed into the stomach. Proficiency in the use of the bronchoscope can be acquired even more readily than in the use of the laryngeal mirror. In the light of this disagreeable experience, the author strongly condemns the use of "comforters."

Some Points in the Treatment of Nervous Diseases.—The special maladies considered by J. Taylor are hemiplegia, disseminated sclerosis, tabes, paralysis agitans, infantile paralysis, and epilepsy. If hemiplegia has occurred from hemorrhage, we must keep the patient absolutely quiet and reduce the blood pressure; but if due to thrombosis, we must stimulate the circulation with strychnine and even alcohol, while purging must be carefully avoided. If syphilis is an element in the case, mercury should be commenced at once, while the iodide should be avoided as tending to lower pressure and to favor clotting. If we can prevent a recurrence of the hemorrhage and inflammation around the clot, a certain degree of improvement may be looked for. But if the heart is hypertrophied and the blood-vessels brittle, a recurrence of the hemorrhage is only too certain. In thrombosis cases, while internal remedies probably cannot render a vessel already blocked again pervious, yet if they are used energetically and periodically it may be possible to remove disease from other vessels, keep them pervious, and prevent subsequent thrombosis. Cases due to embolus in young people generally improve greatly owing to the taking on by the vessels around the affected area of the function of the vessels occluded. In disseminated sclerosis the poison seems to be liberated in a curious periodical way. Improvement often follows rest, regular massage, stimulating electrical treatment, and easily assimilated diet. While this disease is undoubtedly more common than formerly, the diagnosis is often doubtful and it has become the dumping ground of various cases, not all of which are of the classical type. In tabes those cases are most benefited in which the ataxy is the chief and most troublesome symptom. We should improve the tone and coordination of the muscles, and in the author's experience the Fraenkel exercise movements have given the best results. In controlling, or at least modifying, the severity of the tremor in paralysis agitans he has had the best results with hydrobromide of hyoscine, combined with a small amount of strychnine in an acid mixture. In infantile paralysis the effect of drugs in the acute stage is uncertain and doubtful, but after the acute stage has passed marked benefit follows passive movement, electricity, and mechanical support. In epilepsy our efforts should be directed against recurrence of the convulsions, and the bromides are our sheet anchor—sodium, ammonium, or shontium. The potassium salt is no longer used by the author. Petitmal is harder to overcome than the severer attacks. The bromides may be combined with nux vomica to prevent depression or with arsenic to lessen the tendency to acne. The time of administering the bromides must, of course, be determined with reference to the usual hour of attack

British Medical Journal, March 27, 1909.

Bilharziosis of Women and Girls in Egypt in the Light of the Skin-Infection Theory.—A. Looss says that any theory about the mode of infection with bilharzia, in order to be acceptable, must (a) account for the passages of the miracidium both from man to water and back again from water to man; it must (b) duly consider both the habits of the host and the biological peculiarities of the parasite. The theory of the infection taking place by the mouth along with food and drink must be refuted because it is irreconcilable with (a) certain biological peculiarities of the miracidium and (b) with the general distribution of the disease among the population of Egypt. The theory of infection by the miracidium entering the urethra or anus is utterly improbable for general parasitological reasons and in contradiction with a number of biological and anatomopathological facts; for example, the incapability on the part of the miracidium to resist the action of acids even if very diluted, the part played in the infection by the liver, etc. The theory of infection by the skin is in accordance with all the facts thus far known of the biology of the parasite, and the distribution of the disease among the inhabitants of Egypt. It shows how the chief sufferers, the children in town and the adult males in the country, live under conditions which from the epidemiological point of view are essentially the same, and give the miracidia the opportunity of passing within the short time of their life from man to water and from water back to man.

Natural History of Ulcerative Colitis and Its Bearing on Treatment.—H. P. Hawkins analyzes eighty-five cases of that form of bowel disease now known as ulcerative colitis. Of this number twenty were of the short, continuous type resembling bacillary dysentery and in thirty of these the illness was continuous from first to last, with little or no tendency to intermission or improvement. In fifteen of them the disease was fatal, while in the remaining fifteen the illness had lasted from two months to six years, and while they left the hospital still alive it is doubtful if many were cured. In many cases there was a history of dysenteric diarrhea extending over long periods of time. The author asks whether the short attacks and the long-continued cases are one and the same malady. The clinical evidence he thinks is in favor of this unity. He refers also to the hemorrhagic disease or lower segment type, and notes that in ten of his cases simple bleeding from the colon preceded the diarrhea and all other signs of colitis. As to this point, he is inclined to believe that it shows a distinct difference from tropical dysentery, for he has never observed in the latter disease such a stealthy mode of invasion. The severity of the disease and the degree of toxemia vary with the site of the disease in the bowel. In the majority of tropical cases the disease begins in the rectum and iliac colon and remains localized and ascends. In a few cases it begins in the cecum and descends. This latter form presents the more severe results, and a still graver toxic condition exists when the lower portion of the ileum is also affected. The higher the site the more severe and general are the symptoms; the lower the site the milder the symptoms and the more local their effect. The bacteriological evidence as to these various forms of the disease shows that there are three or four groups of cases. Of the author's eighty-five patients forty-one died. From the viewpoint of treatment two classes may be distinguished: (1) Dysenteric diarrhea. Short, mild cases may yield to bismuth and opium, but this is a treatment of one symptom only and not of the underlying condition. Ipecac is not a specific. The best results undoubtedly follow calomel and castor oil. The former should be given in small doses, combined with a little opium. Serum therapy is indicated, but the author has had but little experience with it. (2) Acute and chronic neurotic disease. Here we may use foregoing therapy, but local treatment soon becomes imperative. We have to choose between rectal irrigation, appendicostomy and irrigation, colostomy with irrigation, and artificial anus. The question must be decided from the severity of the toxemia and the probabilities as regards the extent of disease. The author's preference is given to colostomy.

Berliner klinische Wochenschrift, March 15 and 22, 1909.

Hematoma of the Vulva.—Liepmann reports four cases of vulvar hematomata which formed during the parturition and thus acted as an obstruction to the birth of the child. In all cases the rupture of the varicose veins leading to the formation of the swellings occurred spontaneously before any instruments were introduced. In three of the cases the babies were abnormally large, which fact may have determined the rupture of the veins. The duration of the birth act was much increased by this accidental obstruction, and in all cases forceps delivery had to be employed. Episiotomy and incision of the swollen mass had to be done before the instrument could be introduced. Liepmann does not think that varices or the existence of atheromatous changes in the blood-vessels is enough to explain their rupture. The cause lies in the constant pressure upon the vessels by an abnormally large or hard fetal head, the veins being anatomically predisposed to congestion during the birth act. Treatment should consist in forcing delivery before the hematoma has become very large; if the latter has occurred, incision of the swelling must be performed, followed by a forceps delivery.

Early Rising After Laparotomies.—Hartog says that the traditional practice of compelling patients to lie flat on their backs after an operation on the abdominal cavity is slowly passing away. Ries of Chicago was the first to insist upon the advantages of having patients leave their beds as early as possible. Secondary hemorrhage, breaking open of the wound, increased predisposition to hernia at the site of the wound, and finally embolism, have been put forward as the possible dangers of such practice; the first three are prevented by proper technique in closing all wounds made, the latter danger is present after all operations and does not seem to be increased by leaving the bed early. On the other hand, the advantages of this method consist in the great diminution of the danger of secondary pneumonias in the aged, the obviation of the necessity of catheterization and of the use of enemas in most cases, the increase of appetite, and, in general, the rapid recovery of the patient. Hartog's practice is to allow the patients to lie on the side the day of the operation, to raise the head of the bed next day, and to place them in a chair for one-half to one hour two or three days after the operation, if they express readiness to sit up. After this the duration of sitting up is gradually prolonged. Individualization is necessary, for no hard and fast rule can be made for all patients. Uncomplicated and afebrile post-operative course serves as the indication for allowing the patient up.

Wassermann's Reaction in Congenital Syphilis.—Thomsen and Boas have examined many cases of congenital syphilis in reference to the presence of the Wassermann reaction, and have come to the following conclusions: The anatomical examination of the placenta and the umbilical cord, with the examination of the blood according to Wassermann's technique, are sufficient to show whether an infant is or is not suffering from congenital syphilis. A positive reaction with the blood of the mother before labor has occurred makes it probable that the child, too, will be infected. In the organism of an infant, suffering from latent syphilis, there takes place an increase in the materials responsible for the appearance of the Wassermann reaction, which increase continues for the first few weeks of life. The reaction, therefore, if negative at birth, must be sought for later. The reaction seems to be constant in little children having clinical symptoms of syphilis; the same is true of children who are suffering from symptoms of late hereditary infection. It is possible, though not probable, that occasionally the substances that produce Wassermann's reaction may find their way from the mother into the organism of the infant, though the latter is not infected. In such a case the appearance of the reaction in the infant may mislead the physician.

Münchener medizinische Wochenschrift, March 23, 1909.

Pleural Effusions.—Königer says that if purulent effusions into the pleural cavity become early encapsulated, it often happens that serous effusions take place in some of the spaces thus produced. These serous effusions in no way communicate with the purulent effusions; they are free from bacteria and have an abundant cell-content, consisting mostly of polynuclear neutrophile leucocytes with a few lymphocytes and endothelial cells. Most of these cells are well preserved, only a few showing some of the changes characteristic of pus cells. These effusions cannot be explained by the clearing of purulent fluids resulting from sedimentation of their cellular structures. They are, rather, independent serous effusions that mark the inflammatory reaction of the pleura which limits the encapsulated purulent fluid. Very similar pictures are often

seen in abscess in gangrene of the lung, and even in suppuration in the neighborhood of the pleura, such as subphrenic space, liver, etc. Their clinical importance consists in the fact that they render the search for purulent effusions very difficult. An aspirating needle often drains them and thus misleads the operator in reference to the presence or absence of pus in the pleural cavity. Their cellular content, however, should always arouse the suspicion of their true character, and should always lead to further search for empyema.

Deutsche medizinische Wochenschrift, March 25, 1909.

Therapy of Malaria.—Nocht says that malaria belongs to the few diseases for which specific treatment is possessed by physicians. Quinine is the specific remedy; it alters markedly the morphology of most forms of malarial organisms, and destroys them, though some sexual forms prove to be very resistant to the drug. It is, therefore, impossible to cure any malaria by only a few doses of quinine, as the sexual forms give rise to new broods of parasites. Moreover, the female sexual forms of the parasite, the macrogametes, are capable of taking refuge in the spleen, of withstanding the action of quinine completely, and of causing a recurrence of the disease by giving rise to other forms of the parasite. No quinine therapy, therefore, can insure a patient from recurrences, if these mature sexual forms have developed in him. As these forms appear shortly after the infection the practice of waiting for several paroxysms in order to establish the kind of infection before administering quinine is a very pernicious one. The best time for the action of quinine is when most young forms are found in the blood; that is, just before and for several hours after the chill. The drug must, therefore, be given several hours before an expected paroxysm, so that time may be had for the quinine to reach the blood. One gram per day ought to be given and continued for five to seven days. After that the drug is to be given every two, then every four, every six days, and so on. This prevents the development of cinchonism. Six weeks should mark the period of administering the drug, which must be again given in the same way in case of recurrence or reinfection. A modification of this method of treatment is to give quinine for several days, with pauses of two, four, six days, and so on. This seems to affect serious infections much more favorably. Occasionally smaller doses of quinine given for a longer time are as effectual as large doses and should be preferred in treating chronic continuous malarial fevers. Among the preparations that may be used are quinine itself, quinine hydrochloride, quinine bisulphate, and quinine tannate. The latter may be had in almost tasteless form and is therefore well suited for children. Its use, however, does not insure against the appearance of hemoglobinuria in susceptible persons. All hard preparations of quinine, such as pills or tablets, must be tested as to their solubility; many of them are so little affected by the gastric or intestinal juices that they pass through the bowels unchanged and, of course, unabsorbed. There are no substitutes for the specific action of quinine; methylene blue acts much less slowly and not at all as surely. Arsenic and iron preparations are useful in convalescence because of the anemia that often follows malarial infection. The only contraindications to the use of quinine in malaria consist in idiosyncrasy in reference to the drug and the appearance of hemoglobinuria. Nocht concludes by saying that the thorough use of quinine is the whole secret of curing malaria; any continued fever that is not conquered by such therapy is not malarial.

French and Italian Journals.

Spontaneous Infantile Myxedema.—Auguste Beaudry says that although it is admitted that myxedema is caused by the suppression of the functions of the thyroid gland, we are reduced to suppositions to explain the symptoms that result from it. According to some, the thyroid elaborates a useful substance, the absence of which causes the symptoms of myxedema. The other theory is that its office is to remove from the blood deleterious substances, which accumulate when not removed and cause poisoning. In the infant the thyroid plays so important a part in nutrition that its absence causes an arrest of physical and mental development, varying in degree according to the age at which the difficulty occurs. We have congenital myxedema, spontaneous infantile myxedema, and operative myxedema. The author discusses the spontaneous form. The spontaneous myxedema of the infant differs from that of the adult in that its effect begins immediately with a complete arrest of the intelligence, and of the growth of the skeleton. It results in the production of a dwarf more or less of an idiot. If the thyroid action has been early suppressed we have a complete idiot; if suppression has occurred late we get an imbecile. From the moment of suppression the mental development ceases. The dwarf is also afflicted with a solid edema of the skin and mucous membranes. The face is swollen and expressionless. The tongue is thickened, voice hoarse, and nasal mucosa swollen. There is a marked repugnance to movement. Dentition is retarded and incomplete, the fontanelle remains open, the sensibility to cold is increased, and the pulse is small and compressible. Puberty is not established. According to some there is a congenital smallness of the thyroid, which, therefore, becomes insufficient, and since the gland plays an important part in the genital life of the female myxedema is more frequent in females than males. —*Le Journal de Médecine et de Chirurgie*, February 27, 1909.

Prevention of Diphtheria.—Giuseppe Pecori states that the prophylaxis of diphtheria includes various measures, some of them general, some peculiar to the individual, which must be combined intelligently in order to be of real value. The use of diphtheria antitoxin has lessened the mortality of the disease, but it has not lessened the morbidity, because it has made people more careless of contact with the patient. It has been shown that the patient is capable of giving the disease for the entire period during which he has the germs in his throat, which is often many weeks after convalescence has been established. Also the other persons belonging to the family, and the immunized children may carry the germs in a virulent form in the throat for a long time. To disinfect only the room in which the patient was kept for the first few days of the disease is futile, because he has been a carrier of germs for a much longer time. The school is particularly a place where these germs are spread. To have an efficient prophylaxis the author suggests the following measures: Isolation of the patient from the beginning of the disease until the throat and nose are free from germs. Exclusion of the children or teachers in the family from school until an official certificate can be shown stating that bacteriological research has shown throat of the patient and of all the members of the family to be free from germs. Disinfection of the entire house and of the school, and all places in which the patient has been during the disease.—*Gazzetta Medica di Roma*, January 1 and 15, and February 1, 1909.

Orthostatic Albuminuria.—Ernesto Ferraris-Wyss found among 338 children treated six cases of orthostatic albuminuria. He defines orthostatic albuminuria as that type caused in delicate children by the upright position, occurring only in the day time, and disappearing when the child is put to bed. The young patients are pale, have headache, dizziness, nausea, and other symptoms of general debility, but no kidney disease can be demonstrated. No casts or diseased epithelial elements are found in the urine. Autopsy has shown perfectly healthy kidneys when these patients have died of intercurrent disease. According to some authors, there is a debility of the heart present with rapid pulse. Of the nature of the albuminous body that appears little is known. There is nothing abnormal in the ocular fundus. The amount of albumin is one part to one and a half per thousand. Senator attributes this bility of the intestinal walls, congenital or acquired. This condition to circulatory disturbances or abnormal permeability of the intestinal walls, congenital or acquired. This condition does not occur after infective diseases, it is never transformed into a true nephritis; it is often cured; infectious diseases do not seem to be affected by this condition for the worse, the children passing through them like any other child, with no worse kidney complications. From the study of the author's six cases he concludes that this condition is not due to an alteration in the parenchyma of the kidney, nor to a pre-tubercular condition. The cause is probably of a circulatory nature, combined with disturbance of the metabolism of the individual.—*Rivista di Clinica Pediatrica*, January, 1909.

Antitoxin Per Rectum.—A writer in *The Lancet* urges the advantages of the rectal administration of diphtheria antitoxin. The mucous membrane of the rectum readily absorbs the serum. The patient lies on the left side on a couch, and a catheter is passed as far as possible into the rectum; to the catheter is attached the barrel of a glass urethral syringe into which the serum is poured; as a rule gravity is sufficient, but if the fluid does not flow readily the piston can be used in the ordinary way.

Book Reviews.

The History of the Study of Medicine in the British Isles. The Fitz-Patrick Lectures for 1905-06 Delivered Before the Royal College of Physicians of London. By Norman Moore, M.D., Cantab. Fellow of the Royal College of Physicians, Physician to St. Bartholomew's Hospital. Oxford: At the Clarendon Press, 1908.

The Royal College of Physicians of London has played so important a part in the development of medicine in the British Isles that its own history may be regarded as almost an epitome of that of English medicine as a whole. In these four lectures delivered before the Royal College Dr. Moore outlines the growth of medical science from the earliest records to the beginning of the eighteenth century, and has collected a large amount of material that is not only interesting, but should be of great value to future historians. In the first lecture he describes medical study in London during the middle ages, particularly as exemplified in the life of John Mirfield, a London practitioner under the reign of Richard II. The second lecture deals with medical life and study during the sixteenth and seventeenth centuries, and in the succeeding two the development of clinical medicine is traced with more detail, emphasis being laid on the work of Mayerne, Glisson, and Sydenham in England, and on the influence of Boerhave on the methods of the earlier Scotch and Irish physicians. The book abounds in citations from old records, many of which are in part reproduced photographically, and bears witness to the unusual industry of the author in searching the old cartularies and to his skill in deciphering manuscripts. Documents of much interest are the notes by Mayerne on the health of James I and his report on Queen Henrietta Maria drawn up at the time of her contemplated voyage to France in 1641.

Consultations sur la Grossesse, l'Accouchement, les Maladies des Femmes, et les Soins a donner aux Nourrissons. Journal d'un Praticien. Observations personnelles, notées au cours même des événements et commentées. Par H. Stapfer. Paris: Vigot Frères, Éditeurs, 1908.

This volume contains an account of some of the problems and difficulties occurring in the obstetrical practice of the author. Most of the cases are of decided interest, and many of the questions here solved are such as may present themselves to any practitioner. From the nature of the case, the book is much more personal in its tone than any textbook can be. Unfortunately, the cases are stated and discussed without any attempt at either order or arrangement; and the volume closes with an index of little or no value, the references being given, not to the pages of the volume, but to the consecutive number of the "observations."

Primitive Secret Societies. A Study in Early Politics and Religion. By Hutton Webster, Ph.D.; Professor of Sociology and Anthropology in the University of Nebraska. New York: The Macmillan Company, 1908.

This volume is a study of one of the most interesting chapters in Anthropology, namely, the secret societies, and the initiation ceremonies connected with the same. The separate chapters deal with: The men's house; the puberty institution; the secret rites; the training of the novice; the power of the elders; development of tribal societies; functions of tribal societies; decline of tribal societies; the clan ceremonies; magical fraternities; and diffusion of initiation ceremonies. The author has carefully arranged the large amount of material on these subjects collected by many scholars and travelers; and the present book is a suitable introduction to the larger works of Tyler, Frazer, Lubbock, Westermarck, McLennan, and numerous other writers. There are copious bibliographical references, so that the student of this subject can ascertain for himself the grounds on which the author's conclusions are based, and also have a guide for his own future studies.

An Alabama Student and Other Bibliographical Essays. By William Osler, M.D., F.R.S.; Regius Professor of Medicine, Oxford; Honorary Professor of Medicine, John Hopkins University, Baltimore. New York: Oxford University Press, American Branch; London: Henry Frowde, 1908.

Dr. Osler's reputation as an essayist of distinction and charm is too firmly established for the present volume to require eulogies in these columns, and there remains only the pleasant duty of calling attention to its appearance and giving some idea of its contents. As the title indicates, the volume is one of biography, and opens with an account of the life of Dr. John G. Bassett, an Alabama practitioner, during the middle of the last century, and who, though not among the famous, yet shows "that in the simple annals of such a career as the 'Alabama Student' a life may be as perfect as in a Harvey or a Locke." Both of the latter are the subjects of further essays, the one on Locke being made especially interesting by the detailed account of the celebrated operation on Lord Shaftesbury for hydatid cyst of the liver. Thomas Dover, physician and buccaneer, whose name is immortalized in the eponymic of a sudorific powder but who was also an enterprising privateer and the discoverer of Alexander Selkirk, the original Robinson Crusoe; and John Keats, the ill-starred apothecary poet, are the somewhat dramatic subjects of two other essays full of little-known information. New England receives fitting tribute in the appreciations of Oliver Wendell Holmes and Elisha Bartlett, and the influence of Louis on American medicine through the medium of the long list of his pupils from this country who subsequently attained eminence is discussed in another. Under the title "A Backwood Physiologist" Dr. Osler narrates the circumstances under which Beaumont was able to make on Alexis St. Martin the observations that did so much to place the conceptions of gastric digestion on a basis of fact. William Pepper and Alfred Stillé are two more of the moderns to receive graceful acknowledgment from the author's pen, while his essays on Sir Thomas Browne and Fracastorius are evidently inspired by the ardor of the bibliophile as well as the recognition of their prominence in the list of physicians distinguished for literary attainments. The recital of the names of those whose lives have been chronicled in this volume affords a sufficiently alluring promise of its matter, but the full measure of its fascination can be appreciated only by those who have experienced the pleasure of turning its delightful pages.

Textbook of Diseases of the Nose, Throat, and Ear. For the Use of Students and General Practitioners. By Francis R. Packard, M.D., Professor of Diseases of the Nose and Throat in the Philadelphia Polyclinic, and College for Graduates in Medicine, etc. Philadelphia and London: J. B. Lippincott Co., 1909.

This book is written on the basis of an experience of many years of teaching in a post-graduate school. Attention has been paid rather to practical points and their bearing on the everyday work of the practitioner. While only a few students become specialists, some knowledge of these subjects is absolutely necessary to every physician as there are probably no special branches of medical science which come so intimately in relation to the work of the general clinician as these do, and there are none in which a little knowledge may be turned to a more useful account. The foregoing ideas from the preface outline the task set by the author. He has succeeded admirably in its performance. The style is clear, illustrations good, and common sense appears on every page. The reader is not overwhelmed with too much therapeutics. Much is taught, but not too many things.

Surgical Memoirs and Other Essays. By James G. Mumford, M.D.; Instructor in Surgery, Harvard Medical School; Visiting Surgeon to the Massachusetts General Hospital; Fellow of the American Surgical Association, etc. Illustrated. New York: Moffat, Yard & Company, 1908.

Dr. Mumford is already well known as a medical historian, and the present collection of delightful essays can serve but to enhance his reputation as an agreeable and polished writer. In the opening series of chapters, comprising a "Narrative of Surgery," which already forms the introduction to a recently appearing system of surgery, the development of the art is traced as exemplified by the lives of a number of the greatest surgeons. The second essay is a most enjoyable one on "Teachings of the Old Surgeons," in which the author has collected a long series of instances showing that our predecessors, in spite of the fact that in most cases their practice was founded on the purest empiricism that frequently led to absurd conclusions, both recognized and applied many principles that are now considered fundamental in surgical treatment. Then follow several essays on great surgeons, such as Astley, Cooper, Benjamin Brodie, John Collins Warren, Jacob Bigelow, and Samuel Howe, and an address entitled "Studies in Aneurysm." Two more addresses to nurses and one on "History and Ethics in Medicine" complete the volume. Dr. Mumford's knowledge of medical history is profound, and he possesses the ability to make of the lay figures of the past real creatures of flesh and blood, with personalities that are full of human interest. The volume is one that could be read with much profit by all medical students, though perhaps it will be enjoyed even more by maturer minds.

Essentials of Medicine. A Textbook of Medicine for Students Beginning a Medical Course, for Nurses, and for All Others Interested in the Care of the Sick. By Charles Phillips Emerson, M.D.; Late Resident Physician the Johns Hopkins Hospital, and Associate in Medicine, the Johns Hopkins University. Philadelphia and London: J. B. Lippincott Company, 1908.

We have here a book that lives bravely up to the claims of its title page, and justifies its existence in every chapter. In his modest preface the author says: "Many American students lack perspective in their medical studies. They do not learn the A, B, C of the disease first and then proceed to its more difficult study. Our nurses too often know a great deal in a general, indefinite, inaccurate way. They seldom have a clear, sharp mental picture of the elements of a subject." This lack in medical students, nurses, and such of the general public as are interested in the subject is offered the most clarifying enlightenment in this volume, which manages to escape, in some quite wonderful way, the Scylla of dense technicality, without thereby falling into the Charybdis of medical baby-talk. Any layman of ordinary intelligence and application who will take the trouble to familiarize himself with the ground here covered (a pleasant task, for the style is entertaining as well as clear) will have acquired a broad, common-sense perspective on medical questions that will afford him a vantage ground for his whole lifetime. The book is, however, by no means to be despised even by the graduate in medicine, for though it states medical facts in more or less popular phraseology, it nevertheless states facts, and states them more clearly than many a more technically scientific treatise. For the layman who wishes to satisfy his legitimate curiosity regarding the human body and its ills there is no better book existant, as far as the reviewer's knowledge goes, than this.

Tono-Bungay. A Novel. By H. G. Wells. New York: Duffield & Company, 1909.

Any book put forth by so faithful an artist and so tireless a thinker as Mr. Wells is of interest to the intelligent portion of the reading public, his fiction no less than his philosophical retrospect or his daring prophesy. In "Tono-Bungay," his latest novel, he voices again, with sympathy, with humor, with deep insight, the new England of to-day—the *young* England of the twentieth century, reading her mission in terms of the future rather than of the past, rejecting outworn shibboleths, and wafting away the stale air of musty conventions in a breeze of healthy laughter. The men who are writing the books and the plays for this new phase of England's civilization dare to use the language of warning rather than that of blind admiration, and to attack with wholesome merriment certain national traits which filled Carlyle with foaming fury. Lest our readers become too puffed up, we may interpolate that it is not necessary for Americans to cross the Atlantic to examine these traits for themselves. The voices of these latter day John the Baptists are lifted to as good effect on Broadway as in Piccadilly, and "Tono Bungay" by many another name adds its electric glitter to our great white ways.

Apart from its interest as a story, its detailed account of the rise, propagation, and fall of Tono-Bungay, the patent medicine which gives it its name, is the last word of racy witty exposé, and ought to give the *coup de grace* to every advertised colored fluid with which the world is cursed—but it won't. Mr. Wells in his earlier days was a druggist, and his amazing account of the exploitation of this nostrum has a life-like air of reminiscence. "'You see,' said my uncle, in a slow confidential whisper, 'it's nice because of the' (here he mentioned a flavoring matter and an aromatic spirit), 'it's stimulating because of' (here he mentioned two very vivid tonics, one with a marked action on the kidneys), 'and the' (here he mentioned two other ingredients) 'makes it pretty intoxicating. Then there's' (but I touch on the essential secret). 'And there you are! I got it out of an old book of receipts—all except the' (here he mentioned the substance that assails the kidneys), 'which is my idea. Modern touch! There you are!'" But why do we quote? "Tono-Bungay" is a book to read and inwardly digest

Leçons de Clinique Obstétricale (Troisieme Série). Par le Docteur Queirel, Professeur de Clinique Obstétricale à l'Ecole de Médecine de Marseille, Membre Correspondant de l'Académie de Médecine. Paris: G. Steinheil, Éditeur, 1908.

This volume contains about twenty-five lectures on subjects connected with obstetrics. Most of them are on topics which are to be found in the ordinary textbooks, but a few are quite a little removed from the usual run of such lectures. Among these latter we would especially emphasize the lecture on Professional Secrecy. Other important chapters are those on Puerperal Eclampsia, Secondary Hemorrhages, on the harm done by corsets, and Spontaneous Delivery in a primipara with a contracted pelvis.

Modern Medicine. Its Theory and Practice. In Original Contributions by American and Foreign Authors. Edited by William Osler, M.D.; Regius Professor of Medicine in Oxford University, England; Honorary Professor of Medicine in the Johns Hopkins University, Baltimore; Formerly Professor of Clinical Medicine in the University of Pennsylvania, Philadelphia, and of the Institute of Medicine in McGill University, Montreal, Canada. Assisted by Thomas McCrae, M.D.; Associate Professor of Medicine and Clinical Therapeutics in the Johns Hopkins University, Baltimore; Fellow of the Royal College of Physicians, London. Volume V. Diseases of the Alimentary Tract. Illustrated. Philadelphia and New York: Lea & Febiger, 1908.

The diseases of the alimentary tract, to which the fifth volume of this system is devoted, are of such interest and importance to the practitioner as to have justified a special effort on the part of the editors to make their discussion both comprehensive and practically useful. The selection of the colloborators to whom the work was entrusted can meet only with approval, and inspection of the resulting series of articles shows that the writers have evidently all realized the opportunity for serving their fellow practitioners and have made the most of it. The allotment of subjects is as follows: Introductory discussion on diseases of the digestive apparatus, Dr. Charles G. Stockton; diseases of the mouth and salivary glands, Dr. David Riesman; diseases of the esophagus, Dr. John McCrae; functional diseases of the stomach, Dr. Julius Friedenwald; organic diseases of the stomach, Dr. Charles F. Martin; diseases of the intestines, Dr. Alfred Stengel; diseases of the peritoneum, Dr. Humphry Davy Rolleston; splanchnoptosis, Dr. Thomas R. Brown; diseases of the pancreas, Dr. Eugene L. Opie; and diseases of the liver, gall-bladder, and biliary ducts, Dr. A. O. J. Kelly. While the criticism might be made that in a work so largely intended to be one of reference a somewhat more extensive consideration of the recent work on the theory of digestion and its application to metabolic problems, as well as a fuller description of laboratory methods of diagnosis would have been justifiable, it is possible that the available space has been employed in a manner more likely to be useful in everyday practice and therefore of benefit to the majority of readers. That the volume is well adapted to the latter purpose is indubitable, and those who have found reason to admire its predecessors will have no grounds for disappointment in the present addition to the series.

The Systematic Relationships of the Coccaceæ. With a Discussion of Bacterial Classification. By Charles Edward Amory Winslow, Assistant Professor of Biology at the Massachusetts Institute of Technology, and Anne Rogers Winslow. New York: John Wiley & Sons, 1908.

One of the needs of the science of bacteriology at the present day is a satisfactory classification. The older methods were unscientific and bewildering, and most of the modern writers on the subject make use of schematic groupings that are entirely arbitrary. The present volume is an attempt at a classification which shows the natural relationships of the bacteria; and it represents a large amount of independent and personal work done in the laboratory of the Massachusetts Institute of Technology. From the preface we learn that five hundred different strains of coccaceæ were isolated from different sources—from the human body, in health and disease; from air, from water, and from earth. These were submitted to eleven definite and, in most cases, quantitative tests; and the results were analyzed with a view to the centers about which each character varied in the series as a whole, and to the general correlation between different characters. The volume contains chapters on The Problem of Bacterial Classification.—The General Systematic Relations of the Coccaceæ.—Methods adopted in the Comparative Study of the Cocci.—Subfamilies and Genera of the Coccaceæ.—The Genus Diplococcus.—The Genus Ascococcus.—The Genus Streptococcus.—The Genus Aurococcus.—The Genus Albococcus.—The Genus Micrococcus.—The Genus Sarcina.—The Genus Rhodococcus.—Summary of the Genera and Species of the Coccaceæ.—Key to the Genera and Species of the Coccaceæ, and a Bibliography. The authors have performed a real service, and the book will prove a valuable addition to bacteriological literature, both in the laboratory and in the library

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held March 22, 1909.

DR. H. SEYMOUR HOUGHTON IN THE CHAIR.

Control and Prevention of Ophthalmia Neonatorum.—The following resolutions were passed by the society: Resolved: That the item in the supply bill introduced by the Ways and Means Committee of the Assembly providing for an appropriation of $5,000 for the control and prevention of ophthalmia neonatorum and the prevention of blindness as recommended by the New York State Commissioner of Health, Dr. Porter, be approved by this society. Be it also resolved: That official copies of this resolution, signed by the president and secretary, be forwarded to Hon. Jotham P. Alls, chairman of the Finance Committee of the Senate, and to Hon. Edwin A. Merritt, Jr., chairman of the Committee on Ways and Means of the Assembly. It was also resolved that the Medical Society of the County of New York endorses the movement calling for an international congress for the prevention of ophthalmia neonatorum and for the prevention of blindness, and recommends it to President Taft for his favorable consideration, asking that he extend an invitation to the world to participate in a congress to be held in Washington, D. C., in 1910.

Mineral Springs and Gas Well Properties of Saratoga.—The following resolution was offered, but laid on the table: Resolved: That we heartily endorse the bill introduced in the State Senate by Hon. Edgar T. Brackett and in the Assembly by Hon. George H. Whitney, which empowers the State to acquire the mineral springs and gas well properties of Saratoga and to retain them as a State reservation for the free use and benefit of the people of the State of New York for all time to come, such a plan being in keeping with the State and national policy of conserving the natural resources of the country. Resolved: That official copies of this resolution be forwarded to the Senator and Assemblyman named in the resolution.

In Memoriam.—Dr. WILLIAM K. SIMPSON read that for Dr. Andrew J. McCosh.

Dr. L. BOLTON BANGS read that for Dr. William Tillinghast Bull.

Dr. HENRY GRISWOLD presented this for Dr. Robert A. Murray (read by the secretary).

Freezing as a Therapeutic Measure; Liquid Air and Carbonic Acid Snow.—Dr. GEORGE THOMAS JACKSON and Dr. S. DANA HUBBARD presented this communication. (See page 633.) Dr. Hubbard made a demonstration of the carbonic acid snow-making machine and treated several patients before the society.

Dr. CHARLES T. DADE said that ten years ago he read a paper on the use of liquid air in the treatment of lupus erythematosus at the Vanderbilt Clinic; the patient then reported had had no return of the disease. Without doubt the superficial forms of epithelioma could be removed by freezing. Dr. Jackson was right when he gave White the credit of introducing this measure. It was very important to get a crust over the sore, which should be allowed to remain *in situ* and not picked off; this usually fell off in two and three weeks. The pain resulting from the application of this measure was not an intense one; if a baby was treated at the time of nursing he would at once stop crying when put to the breast. All who had used liquid air and carbonic acid snow believed that better results were obtained from the liquid air; where three or four applications were required in using the carbonic acid snow but one application of the liquid air was required to get the same result. Again, thirty seconds was the time to get a certain result with liquid air; to get the same result with carbonic acid snow required one minute and five seconds. In true lupus no good results were obtained; but very good results were obtained in the treatment of the superficial forms of disease, such as the sclerodermata.

Dr. HENRY H. WHITEHOUSE said that his experience had been greater with the use of liquid air than with the use of carbonic acid snow. There was one factor in the first that did not obtain in the snow—the liquid itself, with which the swab was saturated, gave an added effect. So, instead of the three elements in the technique, the accuracy of contact, the amount of pressure, and the duration of the pressure which they had in the carbonic acid snow—they had in the use of the liquid air this other factor, the saturation of the swab with liquid air. Therefore one could get an effect upon larger growths with the liquid air than could be obtained with the snow. In a case he had reported some time ago, a case of epithelioma of the chin and extending to the mucous membrane of the lip, and which had become inoperable, he did not believe the use of the snow would have produced the good result that he obtained from the liquid air. There was a recurrence thirteen months after the first treatment, but this quickly responded to but three applications. It was now over three years since the last application; the patient was seventy-six years old and there was no recurrence.

Dr. JAMES D. GOLD of Bridgeport said that personally he preferred the liquid air, believing that with it he got better results than with the carbonic acid snow. With it the patients complained of less pain and fewer applications were required to get the same effects. He related four cases in which the liquid air had been used with benefit.

Dr. WILLIAM B. TRIMBLE also believed that the effects of the liquid air were superior to those of the carbonic acid snow. Especially good results were obtained in the black-haired nævi. In a large variety of nævi, however, better results were obtained by the use of hot water injections as first described by Dr. John A. Wyeth.

An Operation for Congenital Dislocation of the Hip; Exhibition of Cases and an Instrument Used in Performing the Operation.—Dr. RUSSELL A. HIBBS said that in all cases of congenital dislocation of the hip the head laid above the acetabulum, the great majority posteriorly on the dorsum of the ilium. The fact that the head was above the acetabulum, the shortening of the muscles and ligaments in consequence of this displacement constituted the chief difficulty to the reduction, assuming that the head and the acetabulum were approximately normal. Where there were abnormalities of the bony constituents of the hip joint the cases required special consideration. The dislocation above noted constituting the largest class, was the subject which he discussed. The most successful procedure in this class of cases thus far used was what was known as the Lorenz operation. In this the traumatism was considerable. The procedure he described was first used at the Orthopedic Hospital on April 30, 1907, and was based primarily on the fact that, in a given case, by flexing the thigh upon the abdomen and extending the leg, the head of the bone could be forced downward behind the acetabulum to a point below it. This had been confirmed by means of the *x*-ray in cases up to the thirteenth year. By flexing the thigh extremely in adduction and extending the leg, the muscles were made to exert in some measure the

same pressure in forcing the head downward that they exerted in holding it upward when the leg was in full extension parallel with its fellow, so that in this way the muscles which hertofore had furnished the chief difficulty to the reduction became a most important aid to its accomplishment. The greater tension put upon the muscles by the increase in the length of the limb after reduction made them contribute to the stability of the reduction and obviated the necessity of wearing plaster so long as after the operation of Lorenz. The problem was one of adopting some means to bring the leg back by abduction and extension, so that the head might be forced to travel upward by a more anterior route into the acetabulum. To accomplish this end there must be absolute control of the pelvis, and a trochanteric pad so shaped and held against the trochanter that it would force the head upward and forward. The table to accomplish this purpose he presented. He said he had operated upon thirty dislocated hips and had succeeded in placing the head in the acetabulum and holding it there in all but two cases. Seventeen of these cases were from two to four years of age, seven from four to ten, and six from ten to thirteen. In no case was there any traumatism whatever. The plaster was applied with the thigh and leg in that position which placed the adductors and hamstring group upon tension. The duration in plaster for the cases from the fourth year upward was from four to eight weeks. In those from two to four years, the experimental work led him to the conclusion that the plaster should be worn for three months, being changed at intervals of two weeks, gradually bringing the leg to a straight position. Dr. Hibbs presented four children upon whom he had operated, thus showing the good results he had obtained.

Penmanship Stuttering.—Dr. E. W. Scripture described one case to illustrate a disease of the same nature as stuttering in speech, the difference lying in the fact that the man stuttered in his penmanship and not at all in his speech. The patient was a teller in a bank and explained that he had suffered so much on account of his writing that he had been passed over in promotions and had even thought of giving up his occupation, that a nervous fear seized him the moment he took up a pen. Before beginning to write he would make a number of nervous strokes with the pen without touching the paper. There were cramps of the muscles of action resulting from a compulsive nervous fear that was aroused whenever the action was contemplated. This was the first case of the kind that Dr. Scripture had ever heard of. The therapy was based on the theory of stuttering that had substantiated itself for speech. The stutterer spoke in a peculiar voice that betrayed him to the practised ear even when he did not stutter. This voice was connected with his impulsive idea, namely, with the thought that he was going to stutter. To cure the trouble he was taught to use a form of speech that was entirely new to him, the speech of normal persons. As soon as he understood how normal persons inflected their voices with rising and falling melody and could imitate them, he could speak without stuttering. His voice was changed from a harsh, cramped one to a melodious, easy one. Applying this principle to the penmanship stutterer he sought a method of imparting thought by written characters that would involve graceful and easy movements of the arm and hand. This method had to be entirely different from penmanship and yet capable of gradual change to it Chinese writing brushes were bought, making it possible to use a free and graceful movement of the arm. A new alphabet was devised. It was constantly impressed upon the patient that he was writing in an entirely new way; as long as he had this feeling he would be free from the compulsive idea. The thought of acting in a new way was sufficient. The patient was progressing steadily toward a good cure.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held February 16, 1909.

Dr. Joshua M. Van Cott in the Chair.

The Public Hospital System of Greater New York.—Mr. Robert W. Hebbard, Commissioner of Charities of New York, read this paper. He said that, instead of a hospital system in New York City, there was a woful lack of it. There was the unique spectacle of three different departments of the city government administering the hospitals of the metropolis. They were the Department of Health, the Department of Charities, and Bellevue and Allied Hospitals. There was as much reason for the existence of three different fire departments, or three different departments of police. Thus, tuberculosis in its different forms, incipient, intermediate, and advanced, came under the management of the three distinct bureaus mentioned above. The poor consumptive frequently did not know where to go, in applying for relief, subject as he was to be sent from pillar to post, in this ridiculous subdivision of authority and responsibility. The Mayor of the city had seen this confusion and recently had appointed a commission to consider this subject in all its bearings and to recommend an improved system to the Legislature. This commission had already drafted a report, setting forth the complexity of the situation. It had shown that while in Manhattan $10,000,000 had been appropriated or planned for in the way of hospital construction, not $1,000,000 had been appropriated for Brooklyn, to which the mass of the population was coming. The commission had recommended the extension of the hospital system to Brooklyn, the concentration of the hospitals under one head, and the preservation of the local autonomy of each borough. There had been under construction in Brooklyn a new hospital, the first one to be built by the city in that borough in thirty-five years. This was rapidly nearing completion on Ocean avenue and was to be opened in July, 1909. The duty of nominating the staff of the hospital had been placed in the hands of a committee of the Kings County Medical Society. Besides, the construction of the Bradfrod Street Hospital was soon to begin, as well as the erection of a new wing to the Kings County Hospital. There had also been projected a new pathological laboratory for the Kings County Hospital, and also a nurses' home. The commission was confident that the borough needed a number of emergency relief stations. The cooperation of the members of the Kings County Medical Society was counted upon. Medicine was taking great strides in New York City, and nowhere was this more marked than in Brooklyn Borough. The time was ripe for the medical men of the city to put an end to the lack of system that had prevailed in hospital organization. The Academy of Medicine and the City Club had been advocating the establishment of an ambulance system that would cover effectively every borough in the greater city.

The Biological Foundation for the Specific Therapy of the Infectious Diseases.—Dr. Simon Flexner, director of the Rockefeller Institute for Medical Research, of New York, read this paper. He alluded to the newer conceptions that had arisen as to the mode of con-

quest by the body of the various infections. These were overcome through the operation of the fluids of the body and the mobile cells, the phagocytes. The latter comprised two classes, leucocytes that dealt with bacteria, and those that were not so mobile and dealt with tissue elements that had suffered. In the blood there were also substances originally called alexins, which had the power of neutralizing the parasites that invaded the body. Alexins could better be defined as the equivalent of the complemental substances that acted between the bacteria and other substances in the blood and brought about the destruction of the former. The term alexins was originally applied by Buchner to the defensive principles in the body. These were normally present in the body. It was found to be relatively easy to produce outside of the body antitoxins, the introduction of which inside the body would serve to overcome the toxins produced by microorganisms. But in the case of the intracellular toxins, in which the infectious agent was bound up with the cell and did not exert its influence apart from the cell itself, it was not possible to produce antitoxic substances easily. The poison was freed only by the destruction of the cells. In case of recovery from a bacterial disease a second attack rarely occurred. An apparent contradiction to this statement seemed to be suggested by the occurrence of a relapse in typhoid, but here it was quite probable that the secondary attack was paratyphoid and not true typhoid. Recovery left behind in the body a relative degree of immunity. Although the biological foundation of immunity was well understood, that form of immunity in which the organism produced extracellular toxins had been more thoroughly investigated and understood than the form occurring in infections with organisms of the other type. Various parts of the body possessed unequal immunities. This was suggested by the manner in which infections tended to localize themselves. For example, typhoid was localized in the intestinal tract and the meningococcus in the central nervous system. The localization of infections was to a certain extent the expression of the mode of entry of the organisms into the body, but to a greater extent it was the indication of the varying degrees of resistance offered to the organisms by the different parts of the body. Thus the tetanus poison, which could enter at any point, localized itself in the central nervous system. But it had been found possible artificially to increase the immunities in particular regions, such as the connective tissue, with reference to the tetanus bacillus. Thus, when spores of this organism were introduced into the subcutaneous tissues, mixed with eosin, which confined their activity to the region injected, it was found that by means of repeated injections the connective tissue could be immunized; the tetanus poison could no longer enter the body through that tissue. The same result could be accomplished with the typhoid organism, in which a particular locality of the body could be brought to a higher degree of reactive immunity than the body as a whole. In the different forms of localized immunity the cells were left in a modified form. It had been sought to get some points of the manner in which the body brought about spontaneous cure. If one studied from day to day the course of healing in cerebrospinal meningitis, there would be noticed a diminution of viable meningococci existing outside of the leucocytes, and the diminution of the cells themselves; this was coincident with the clearing up of the infectious process. It was desirable to produce artificial means for promoting the same phenomenon. If an animal was immunized, a relatively small amount of antitoxic substance was produced. Other principles were generated which were not antitoxins; they had not the power of neutralizing toxins, but acted like lysins, opsonins, etc., and were effective when brought into contact with the organisms in a confined space. One of the main reasons for failure in this form of warfare against infectious organisms was that there was no means of bringing these agents into relationship with the microorganisms in a state of sufficient concentration. When injected into the blood-stream their uniform diffusion over the body prevented the attainment of this state of concentration. In places readily accessible, like the meninges, pleura, and the interior of the joints, it was conceivable that such a concentration might be attained. The ideal treatment was the serum treatment, the products used being the specific reaction products to the particular germs. These were the parasitotropic substances which were not injurious to the cells of the host, although they were not always effective against the parasite. It was unfortunate that it was not always possible to prepare these substances in a state of sufficient concentration. The future of serum therapy depended upon a better understanding of the resistance offered by the body to threatened infection, and of the phenomena that occurred in a spontaneous recovery. The question then presented itself: What was immunity that was not antitoxic? The knowledge of antitoxic immunity was so considerable that it was possible to predicate the degree of infection, its duration, and the localization of the process. On the other hand, the knowledge of immunity to microorganisms that did not produce extracellular toxins was slight. In the presence of these organisms one's attitude was to a certain extent hopeless. We were no further advanced than before the bacteriological era. Efforts to combat these organisms had been to a certain extent useless; on the other hand, they tended to eliminate themselves and the resulting immunity was considerable and lasted for many years. Undoubtedly the next step in advance was to get a closer understanding of the rebellious agents belonging to this class of infections. In combating them there was a new form of therapy which the speaker now desired to discuss. This was chemotherapy. This was, to be sure, an old form of treatment, as exemplified by the use of quinine in malaria and mercury in syphilis. But these were both instances of empiricism. The facts relating to specific chemotherapy had been worked out experimentally in the chemical and pharmacological laboratories. The beginning went back to twenty years ago, when Ehrlich began his investigations on the dyestuffs. He had found that methylene blue and neutral red had a selective action on certain parts of the body. The investigation of the relation between the dyestuffs and the cells became the basis of the side-chain theory. The dyestuffs were again coming to the front in the treatment of experimental trypanosome infections. It had been found by Koch that the aniline compound atoxyl was of curative value in the treatment of that form of trypanosome infection known as sleeping sickness. The disadvantage of its use was the fact that it occasionally produced blindness. Another objection was that the trypanosomes not destroyed tended to become more virulent than before. About this time Ehrlich took up the study of trypan red, which had been found so effective a cure in certain cases. Experiments with this suggested that it might be possible to so increase the efficiency of atoxyl as to increase its parasitotropic and reduce its organotropic properties. The object was to learn to shoot straight with the drug. The introduction of the glycocoll radical seemed to fulfill these requirements. This form of therapy was applicable not only to trypanosomiasis, but also to relaps-

ing fever, tick fever, and possibly also to syphilis. Mercury was, of course, a successful but not an ideal specific. Syphilis could be inoculated into monkeys and into the lower but not the higher apes. The direct inoculation of the syphilitic virus over the eyebrow of the macacus produced a lesion indistinguishable from the human lesion, and also persisting for two years. In the lower monkeys there were no secondary manifestations. The lesions remained localized. If a series of animals were taken, and inoculated by means of scarifying the skin over the eyebrows and rubbing in the virus, the lesion would be developed in four weeks. If two or three grains of atoxyl were given on the day following or as late as fifteen days following the inoculation, the disease would be prevented. The animals were not immunized, but simply protected. Reports of the use of this drug as a substitute for mercury did not give results that were as yet satisfactory. The modifications which atoxyl had undergone might make it more effective in syphilis, as it had in trypanosome infections. The Wassermann reaction was a valuable aid in the diagnosis of syphilis. Its principle depended upon the presence in the blood of infected individuals of an immune body. Dr. Noguchi had prepared the various factors of this test on bits of absorbent paper. The essence of the Wassermann reaction consisted in the fact that the blood serum of a syphilitic patient had its complement fixed when brought into contact with the extract of the liver of a syphilitic fetus. When such a mixture was added to the blood serum of a guinea pig which had been immunized to the human red blood cells and then heated so as to destroy the complement, the result was that no hemolysis occurred. On the other hand, the blood serum of a healthy individual, when mixed with the extract of liver of a syphilitic fetus, had its complement free. When further mixed with the heated immune serum of guinea pig and human red blood cells, the free complement caused hemolysis to occur. The necessary factors in the Noguchi modification of the Wassermann reaction were as follows: A drop of human blood, a drop of serum from a syphilitic patient mixed with salt solution; heated blood serum of the guinea pig immunized to human red blood cells, and the antigen, consisting of the extract of the liver of a syphilitic fetus. The three last were mixed and incubated in a tube carried in the vest pocket. When mixed later with human red blood cells if syphilis was present no solution of the cells took place but if syphilis was absent the corpuscles were dissolved. In the former case, the test being performed in a test tube, the intact corpuscles falling to the bottom of the liquid, this became clear; in the latter case, the destruction of the corpuscles caused a clouding of the liquid. The test was positive in 90 per cent. of suspected cases of syphilis, and as treatment was successfully carried out the reaction tended to disappear. This method was therefore a valuable criterion of the efficacy of treatment. By means of it relapses could be predicted even before the obvious physical evidences appeared.

NEW YORK ACADEMY OF MEDICINE

SECTION ON PEDIATRICS.

Stated Meeting, Held March 11, 1909.

DR. ELI LONG IN THE CHAIR.

A Case of Exophthalmic Goiter in a Girl Ten Years of Age.—Dr. M. NICOLL, JR., presented this case. The clinical data regarding the case were insufficient because observations had been made only during a week or two. The father was an Austrian Jew, forty-three years old, and had been in this country thirty years. He was a moderate drinker and probably an excessive tobacco chewer, but denied ever having had venereal disease. The physical examination was negative, except as giving evidence of a highly nervous mental condition, and a slight tremor of the face when speaking. His eyes readily filled with tears. The action of his heart was normal. The mother came from the same country as the father, had been married twenty-three years, had seven living children, and no miscarriages. The two youngest children, three and six years of age, seemed normal, and one girl of nineteen was said to be strong and well. The oldest boy had gone to City College for four years, but had given up work because of nervousness and weakness for the past three months. His thyroid gland at the upper part showed no hypertrophy, but his eyes had the prominence of his father's. His pulse was between 120 and 142 when he was seen at the clinic. A fourteen-year-old girl was said to have frequented the clinic for years to be treated for asthma. She had a chronic emphysema and when first seen had a typical asthmatic attack. These attacks came on in damp, rainy weather. Her pulse had ranged between 120 and 165, the latter during an attack of influenza. If there was an enlargement of the thyroid it was not palpable. A ten-year-old sister came to the clinic to have her eyes treated. She seemed to have an exophthalmus, fairly well marked von Graefe sign, and marked pulsation of the retinal vessels. The thyroid was distinctly enlarged. The patient was moderately nervous, but attended school regularly. Her pulse varied from 120 to 145. Her urine was normal.

DR. JOHN ROGERS, JR., said that the apparent heredity in these cases and the diagnosis was of interest. He believed that heredity increased the susceptibility. The parent might transmit a certain amount of weakness in certain organs or perhaps a diathesis. In the diagnosis of exophthalmic goiter there seemed to be one characteristic "fatigability," and the nervousness brought on by a little emotion or strain. He thought the condition could be made worse or better by the administration of thyroid or thyroid products. Dr. Riggs had been working in the Cornell laboratory for two years endeavoring to determine the iodine content of the thyroid gland and had proven that the ideas in regard to this were erroneous. In exophthalmic goiter the proportion of iodine to the weight of the gland was very much less than normal; this diminution was in direct proportion to the severity of the disease. This was probably due to some defect in the gland, which caused a failure to take up the iodine. These patients could be made better or worse by the administration of small doses of iodine, which showed their susceptibility to this agent. The various defects presented by the different members of this family, one having asthma, another headaches and constipation, another being feeble, and the father showing mental defects, seemed to indicate that the thyroid was intimately connected with nearly all the organs of the body. Any strain on the nervous system made the disease worse and any disorders of the digestion aggravated it. In fact, any intercurrent affection seemed to make the disease worse. He believed that this gland was concerned in the fundamental chemistry of every organ and tissue in the body and that it had an "activating" effect upon each. Both the quantity and the quality of the secretion had to be considered in every case. In some cases the quantity of the secretion was too great and had to be cut down by means of surgery or by a specific antiserum. In other cases the quantity was not in excess, but the quality was impaired and had to be "helped out," as it were, by one or another of the pure thyroid proteids, or by iodine. Every effort should be made to

improve the general nutrition, as this in turn affected the thyroid and the quality of its output.

A Case of Inoculation Tuberculosis Following Ritual Circumcision.—Dr. Sara Welt-Kakels presented a baby, six months old, born of healthy parents and breast-fed, in which there was no history of lues or tuberculosis. The parents had been married four years and had one other child, who was healthy. The baby was born at full term and at birth had been slightly asphyxiated. On the ninth day he was circumcised according to the orthodox Jewish ritual. The wound was sucked by the operator, who had followed his occupation for the past thirty years. He had a cough, and, in all probability, tuberculosis. Afterward the wound looked inflamed and the surrounding parts red and swollen. The child seemed feverish and suffered from a slight digestive disturbance. Some four weeks later the mother noticed a swelling in the left groin and consulted a physician, who prescribed an ointment. No improvement followed its use. In December the child was brought to Mt. Sinai Dispensary, showing a small hydrocele on the right side and a glandular swelling in the left groin. When the woman returned again some weeks later the prepuce looked edematous, a slight nodule was felt in its periphery, and fluctuation was felt in the glandular swelling. This was aspirated and a thin serous discharge, mixed with flocculi, escaped. Tuberculous infection was then suspected. Von Pirquet's test gave a positive reaction. The discharge was examined by Dr. Bernstein, who reported the presence of typical tubercle bacilli. In the latter part of February the enlarged and partly suppurating glands were removed under chloroform. Some of them were adherent and brittle, and had to be removed with the curette. A chain of glands situated near the large vessels were also removed *in toto*. Dr. Bernstein reported that sections of the glands showed tubercular giant cells, with areas of cheesy degeneration. Tubercle bacilli were also detected by the usual methods. The child was well fed, weighed 19½ pounds, looked rosy and happy; this was a living refutation that tuberculosis in infancy led to cachexia and marasmus. The temperature was normal and also the thoracic organs, although a few râles could be heard over the lungs. The spleen was still slightly enlarged, and, while there was still a deep sinus in the left inguinal region, it was gradually filling up with healthy granulations. It appeared from a study of inoculation tuberculosis following ritual circumcision reported in current literature that these cases were frequently looked upon as syphilitic, and valuable time was lost while employing specific remedies. It was important to make a careful diagnosis on account of the tendency of tuberculosis in infancy to become generalized, and this could easily be done by means of the microscope and the newer methods of examination. The prognosis of the case was dubious if one considered the great disposition to selection so characteristic of tuberculosis in infants. The outcome would depend on whether the process had been confined to the inguinal lymphatic glands or whether it had progressed to distant organs. The literature seemed to indicate that cases in whom recovery had apparently taken place afterward developed fatal tuberculous lesions. As Dr. Knopf had recently suggested, only persons who had shown the necessary skill before a medical board of examiners should be allowed to perform circumcision, and they should submit themselves to a medical examination every time they were called upon to perform this rite. Dr. Willy Meyer believed with Professor Maas that it was the duty of physicians to protest against ritual circumcision.

Dr. Henry Koplik said that while these cases of inoculation tuberculosis occurred occasionally they were becoming more and more rare, as the men who performed this rite became more enlightened. These men in New York City were as a rule careful and did their work with the necessary surgical precautions. While Dr. Koplik was in charge of the Good Samaritan Hospital and Dispensary he saw many of these cases and they were properly diagnosed as tuberculous. Dr. Koplik recalled a case that he had seen with Dr. Ware, where the child had but little constitutional disturbance and a slight cachexia. The cachexia usually appeared later and these children, as a rule, went to the wall, developing other forms of tuberculosis. Among the cases that he had seen, the earliest appeared three months after circumcision.

Dr. Charles Goodman said that the danger of the ritual circumcision lay in the old traditional custom of practising the act of sucking, after the prepuce had been divided. The purpose of this was not definitely understood, but was explained by some Hebrew writers as being hemostatic and styptic; by others as having a cleansing action, preventing inflammation of the wound. The dangers of this practice had been brought to notice in other countries. In 1845 the French Government permitted only Mohels properly qualified by instruction to perform circumcision, and at the same time abolished the suction part of the rite. In German Austria, and in other countries, the suction was performed with the aid of a cupping glass, thus permitting of all the traditions of the ritual of circumcision without the danger of infecting the infant. A case of syphilitic infection was reported in 1811 by Krakow. In the early years of Dr. Goodman's practice he insisted upon having the mohel brought to his office; here he gave instructions and warned him not to do suction without the circumcision glass. The licensing of only competent and properly instructed mohels would do away with the dangers to the innocent offspring.

Dr. Martin W. Ware said that after a period of incubation of four weeks the glands enlarged and the lesion assumed the characteristic appearance of a tuberculous sore, thus coinciding with the first appearance of the luetic adenopathy; the sore could pass for either one of lues or tuberculosis, thus rendering the clinical diagnosis somewhat difficult. The condition appeared to be on the wane. At such a tender age the glands were found to be extensively involved and the removal of them constituted a capital operation; after operation for tuberculous adenitis, the children did badly. Dr. Ware reported an interesting case of a child with inoculation tuberculosis of the lobule of the ear, due to piercing the ear with a needle and thread, after the thread had been moistened by the saliva of a tuberculous nurse.

A Case of Diabetes in a Boy Ten Years Old.—Dr. Henry Heiman presented this patient. The trouble began five months ago with thirst, increased appetite, increased frequency in urination, and loss of weight. The urine had a specific gravity of 1,032, the daily amount passed was 5,700 c.c., and sugar amounted to 285.0 in twenty-four hours. There were a few small hyaline, finely and coarsely granular casts and some epithelial cells. When Dr. Rudisch was requested to assume charge of the patient he ordered a diet which represented proteids 88.65, carbohydrates 29.72 and fats 114.12, representing a caloric value of 1,633.0. Atropine methylbromide was first given and then the sulphate was sbustituted. To-day the boy was caring for 105 grams of bread daily and without any disturbance in the sugar metabolism. What the ultimate outcome

could be in this case Dr. Heiman would not state. The boy had gained in weight and the sugar had disappeared entirely from the urine.

Dr. Rudisch said this case was of particular interest because of the age of the patient; in such young persons the prognosis was usually considered very unfavorable. This child of ten years, with diacetic and oxybutyric acids in the urine, taking carbohydrates all the time at home, he continued on a limited diet of carbohydrates, but the diacetic acid would not disappear from the urine. In such cases all authorities agreed that a certain amount of sugar was indicated; therefore, he gave the child fruit, hoping that the levulose contained therein would not be deleterious as starch or dextrose. He then gave the patient an absolutely strict diet of proteids, including meats, fish, and such vegetables as contained small quantities of starch, especially cabbage. To satisfy the boy's hunger, quantities of cabbage and other bulky vegetables were given. The boy's stomach must be kept full, or he would complain. Under this diet the diacetic and oxybutyric acids disappeared from the urine, proving that the presence of these acids was not always a contraindication to a strict protein diet, contrary to the opinions of most authorities. A little fat in the form of oil, not butter, was given. From his experience, he had found that one could decrease the amount of sugar excreted and increase the tolerance for carbohydrates more rapidly by the adminstration of atropine salts combined with diet than with diet alone. Sulphate of atropine should be given, commencing with small doses, and increased very slowly. The polyuria in the patient presented by Dr. Heiman had diminished, and he was passing now 2,000 c.c. of urine daily, whereas he had passed 5,000 c.c. before treatment was instituted. The prognosis in these cases was dubious, and the treatment must cover a long period of time. These patients should be kept where they could be watched with care, because they would use every means to obtain crackers, bread, and the like surreptitiously.

Pneumonia; A Bedside and Laboratory Study.—Dr. Augustus Wadsworth presented this paper. He said that he had found the study of experimental pneumonia very interesting and instructive. Other organisms besides the pneumococcus had been found as incitants of pneumonic infection, but, with improved technique and more extended study of the cases at autopsy, the importance of the pneumococcus had been more and more fully disclosed. Streptococci as primary incitants of lesions were less frequently found except in certain of the so-called secondary pneumonias of the exanthemata. Both streptococci and pneumococci were found in lung lesions; when the etiology was thus obscured precedence as a primary incitant should be given to the pneumococcus. Friedländer's bacillus was now thought to be more often a secondary or complicating, than a primary, incitant of the disease. Dr. Wadsworth said that in 1902 he had begun his researches designed to determine the effect of cultures of pneumococci of known but varying grades of virulence, when introduced under the skin, into the ear vein and through the trachea into the lung. These inoculations were made in normal rabbits, in rabbits predisposed systematically by poisoning with phenylhydrazin, in rabbits predisposed locally by injury to the lung through exposure to cold, and as the result of the introduction of foreign material directly into the lung, and finally in rabbits predisposed both locally and systematically. He had observed the following results: Subcutaneous and intravenous inoculations were harmless with cultures of inadequate virulence, or with virulent cultures the results were fatal from either quick or prolonged bacteriemia. In these experiments significant lung lesions never developed. Endotracheal inoculations alone gave rise to lesions comparable to pneumonia in man, but these varied greatly. Cultures which proved fatal when introduced under the skin or in the vein, frequently proved harmless when introduced through the trachea. Predisposition accelerated the development of the infection and its course. With virulent cultures the lung changes were less in extent and the bacteriemias were rapidly fatal. Bronchopneumonic types of reaction only were obtained when virulent cultures were used. Extensive lesions of the lobar type were obtained only when both the general system and the lungs were predisposed, and organisms of very low but sufficient virulence were introduced through the trachea; this balance of conditions was secured only with difficulty in the normal or predisposed rabbits. In order to secure exact experimental conditions, extremely virulent cultures of the pneumococcus were introduced through the trachea of the rabbit already partially immunized to this organism. Under these conditions extensive lesions, comparable to the diffuse pneumonias of man, were more often obtained. Experiments with the dog, which was naturally less susceptible to the pneumococcus, supported very strikingly these observations.

By means of systemic study with controlled conditions that would admit of accurate and significant comparison, it was possible to interpret the results of previous researches and to suggest with reasonable precision the subtle balance of conditions of bacterial virulence and tissue susceptibility underlying the different types of pneumococcus infection in man. Reactions of the bronchial type developed more frequently in conditions of greater susceptibility, while the lobar type occurred in conditions of lesser susceptibility or greater resistance. Examination of the blood had revealed the presence of the pneumococci and suggested that bacteriemia occurred in all stages of the disease and was possibly a constant factor in all cases. The finding of the bacteria in the blood proved that bacteriemia was an essential part of the disease, and not that lung lesions were due to them. Man constituted the chief source of the pneumococci, but streptococci were to be found everywhere. Virulent pneumococci were found in the mouths of from 20 to 30 per cent. of the inhabitants of our cities. Under the auspices of the Commission for the Investigation of Acute Respiratory Disease, appointed by the Board of Health of New York City, Dr. Wadsworth had taken up the problem of mouth disinfection in the prophylaxis and treatment of pneumonia. Complete disinfection of the mouth proved impracticable. This conclusion had been reached by almost every student of the problem. A mouth wash should be bland, nonirritating, isotonic, slightly alkaline, should diffuse readily with the secretions and cleanse the mucous membrane. It should possess disinfecting properties as well. The only solution which fulfilled these conditions to any satisfactory degree was one containing 20 to 30 per cent alcohol, 5 to 10 per cent. water, salts, and flavoring oils. At present attention could only be directed to decent care in coughing and sneezing, reasonable isolation of the sick, the hygiene of the mouth and pharynx, and the care of these secretions. Experience had tempered the concern caused by extensive lung involvement, except where there was mechanical interference with respiration endangering life; the serious signs and manifestations of the disease were not referable to the lung. The serious respiratory signs were those due to failure of the circulation. At autopsy

the fact was revealed that despite the large amount of exudate in the inflammatory processes the pneumococci were rarely numerous. Laboratory and bedside experience suggested that virulent pneumococci gaining access to the lung and there finding conditions favorable, developed with astonishing rapidity, inciting inflammatory exudative reactions and elaborating toxic products, which were rapidly diffused. Involvement of the general system then ensued; the onset of the disease was evidenced by a rise of temperature together with a chill.

The eosinophiles disappeared during the febrile period, returning just before the crisis or with it. Agglutination reactions varied just as in other diseases. The heroic measures of clinicians at the bedside failing to yield satisfactory results, attention in recent years had turned to the laboratory and to the student of immunity and serum therapy. An antitoxin was first sought, but in the absence of a toxin this was impossible. The use of watery extracts of leucocytes obtained from aleuronat pleurisies of the rabbit had been advocated, but, in his experience, this prolonged the course of the experiment and might save the animal, but only in infections of not too great virulence. To meet the indications obtaining in individual cases and to avoid the adoption of those measures which might interfere with the development of the immunity upon which recovery ultimately depended was no light task. One often hesitated, and when in doubt it was best to do nothing, or, as Dr. Northrup wisely said, open the window and feed the patient properly. Drugs were to be avoided except in the correction of errors of circulation or digestion, or for the comfort of the patient. The clinician and the research worker were mutually indebted to one another for much that was valuable in their several studies of pneumonia. Clinical data lent its practical suggestions to laboratory work, often serving to check useless effort and clearing the imagination of the vagaries to which theory was prone to fall a victim.

Dr. David Bovaird, Jr., said that the vital statistics of pneumonia showed that it was one of the acute infectious diseases which was not under control at the present time. The vital statistics of England for ten years showed that the number of deaths from contagious diseases had remarkably diminished, but that the number of fatal cases of pneumonia showed an increase. On the Isthmus of Panama pneumonia was the one disease that gave the greatest fatality. Greater importance should be given to the bacterial infection of the blood; these patients suffered from bacteriemia, rather than from consolidation of the lungs. On the one hand, children or elderly persons were seen with extensive consolidation of the lungs, who scarcely considered themselves sick and presented no evidences of serious illness. On the other hand, they met from time to time an individual in excellent health, very strong, taken down with a pneumonic process in which the extent of the pneumonia was slight, yet such a patient would become deathly sick and die of the pneumonic infection. Clinical and pathological observation also showed that death from an uncomplicated pneumonia was really a rare occurrence. On the autopsy table there would be found other lesions than pneumonic, such as an endocarditis, or a secondary invasion of the pneumococcus in the form of an extensive pleurisy, or pericarditis, or meningitis, etc. The point that impressed itself upon him was that, given a pure lobar pneumonia, uncomplicated, one would expect the patient to recover. On the other hand, the fatal cases showed some additional invasion of the pneumococcus.

Philadelphia Neurological Society.

At a stated meeting held March 26, Dr. Alfred Gordon reported "A Case of Infantile Hemiplegia with Unusual Symptoms." He reported also "A Subdural Abscess Followed by Internal Hydrocephalus," and he presented the specimen. Dr. J. H. W. Rhein reported a case of progressive muscular atrophy following a fall upon the arm, the symptoms appearing first in the injured member. Dr. Chas. W. Burr reported "A Case of Brachial Palsy," developing with such abruptness as to suggest the possibility of hemorrhage into the spinal cord. It was, however, decided to be due to peripheral neuritis, and post-mortem examination confirmed the accuracy of this opinion. Dr. Burr exhibited "A Brain from an Epileptic." The organ was diminutive, but presented no other gross lesion. Dr. Burr exhibited also "A Brain from an Aphasic who had Largely Recovered." In the left hemisphere was an area of softening involving the basal ganglia and the internal capsule, but the cortex and especially Broca's convolution were unaffected. Dr. D. J. McCarthy exhibited "A Brain from a Case of Adenolipomatosis Showing an Accidental Complication of Cerebral Arteriosclerosis." The specimen illustrated the manner in which thrombosis may occur in the cerebral vessels in connection with vascular hypertension. The displacement of the vessel resulting from the high tension changes the angles at which branches arise, and this alteration in the course of the blood-stream may readily be attended with the formation of a thrombus. In the specimen exhibited the tenth nerve on one side was considerably displaced by the looping of a branch of the basilar artery. Dr. Horace Carncross demonstrated a patient presenting "Cramps Resulting from the Involuntary Use of Voluntary Muscles." The patient was an athletic young man who had developed the habit of contracting the vastus muscles and who presented clonic contractions in these muscles and suffered from cramps in the calves of the legs, with varicose veins in the right thigh and leg. It was thought that all of the phenomena were closely related. Dr. D. E. Robinson exhibited a patient presenting "Choreiform Movements of the Abdominal Muscles." The patient was an elderly man who had been struck by a crowbar many years before, and in whom there developed involuntary jerking of the muscles of the abdomen in the umbilical region, intensified by excitement and ceasing during sleep. Dr. Hideyo Noguchi gave by invitation "A Demonstration of a New and Simple System of the Complement Fixation-Test and of the Butyric-Acid Test for Syphilis and Parasyphilitic Affections." He explained the rationale and the method of applying the Wassermann test for syphilis, pointing out the difficulties of technique and the liability to error. He had been able to simplify the test so that it became possible for anyone, even though he did not possess any special skill or training, to apply it. Dr. Noguchi also described a test which he had devised for the detection of parasyphilitic affections, such as general paresis and tabes dorsalis. In performing this test he said he added to cerebrospinal fluid obtained by lumbar puncture a 10 per cent. solution of butyric acid in physiological sodium chloride solution and then neutralized with sodium hydrate solution. A flocculent deposit represented a positive reaction. Dr. Noguchi said that this test was not specific as was that for syphilis. Dr. Joseph Aronson then presented an interesting report of "Two Cases of Folie à Deux," occurring in mother and daughter. These two women had gone from place to place because they thought they were being pursued by certain persons with evil designs. Both mother and daughter exhibited similar delusions. The younger woman was a high-grade imbecile. Under treatment the daughter improved greatly, but very little appreciable change was brought about in the condition of the mother.

Pathological Society of Philadelphia.

At a stated meeting held March 25, Dr. Courtland Y. White presented a specimen of perforate interventricular septum and incomplete closure of the foramen of Botal. The heart came from a child three years old dead of croupous pneumonia and at no time presenting evidence of being a blue baby. Both ventricles were hypertrophied, the left being the larger and its walls the thicker. Between them, just below the auriculoventricular septum was an opening of communication about 2 cm. in diameter. In the interauricular septum there had been failure of the fold of endocardium to unite, although their margins overlapped. The pulmonary artery was considerably enlarged. Dr. White exhibited also a specimen of inflammation of the heart from a child eight years old. The pericardium was thickened and adherent in parts, with deposits of plastic exudate also in places, and there were vegetations with beginning ulceration, on both mitral and aortic leaflets. Dr. H. S. Wieder exhibited a specimen of "Congenital Misplacement of the Kidney." The organ came from a dissecting-room subject and was situated on the left side at the brim of the pelvis. The renal artery came off at the bifurcation of the aorta and the veins entered the ascending cava. The pelvis and ureter were short, and there was every reason to believe that the kidney had been in its unusual place since birth. The opposite kidney had undergone compensatory hypertrophy, but it was in other respects normal. Dr. John Speese read a paper entitled "Pure Adenoma of the Breast." He reported the case of a woman twenty-one years old in whom a small tumor of the breast previously present underwent considerable and rapid increase in size with the beginning of lactation and for this reason was removed. On histological examination it was found to be an adenoma with a minimum amount of fibrous trabeculæ. The growth is given little consideration in the text-books and few cases have been fully recorded. Fibromata and fibrolipomata are more common. Dr. F. M. L'Engle presented a communication entitled "The Flagellation of Leucocytes in the Presence of Chemical Excitants and in Other Conditions; A Preliminary Report." He reported observations confirmatory of those already made by others showing that under the conditions mentioned leucocytes in the circulating blood undergo flagellation, and he suggested that this phenomenon might have something to do with the reproduction of leucocytes. Dr. J. W. Hunter presented a communication entitled "The Structure of Inoculable Mouse-tumors with Special Reference to their Histological Variations."

Contribution to the Knowledge of Traumatic Neuroses: Diplegia of the Face of Hysterical Origin Due to Wound by a Dagger.—Augusto Di Luzenberger records a case of facial diplegia resulting from wounding of the face and neck with a dagger in the hands of the patient's father. She was cured of the wounds, which healed well, but there remained anesthesia and facial diplegia. The patient was not emotional, and did not show the ordinary character of an hysteric. When the examination was made it was found that there was blindness of the left eye, absence of smell on that side, and lessened hearing. The right eye showed concentric narrowing of the visual field. The ocular movements of the eyes were good when made together, but those of the left could not be made when the right was closed. The electrical examination of the facial muscles showed a normal reaction. Galvanofaradic treatment caused a cure of the troubles. True hysterical paralyses of the facial nerve are rare. It may be simulated by spasm of the angle of the mouth. This form is of psychic origin. In the brain are centers corresponding to groups of muscles which are in correlation with one another. When the condition is normal the impulses connecting these areas pass rapidly and without pain. But when these centers are disturbed there is pain and inability to correlate the movements which results in a psychic paralysis. This lack of correlation is frequently produced by trauma. — *Annali di Elettricita Medica e Terapia Fisica*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 10, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	683	196
Diphtheria	309	49
Measles	953	32
Scarlet Fever	353	23
Smallpox	—	—
Varicella	119	—
Typhoid Fever	15	—
Whooping Cough	42	6
Cerebrospinal Meningitis	8	8
Malarial Fever	—	—
Totals	2482	314

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending April 9, 1909:

SOME REMARKS ON THE PRACTICE OF MEDICINE AS A CAREER.

BY A. JACOBI, M.D., LL.D.,

NEW YORK.

MUCH has been said about our duties to other men, the community, the State, and mankind. Correctly so: I approve of every encouragement of beneficence and altruism. The physician was made for the people, like the public officer who exists for his office and its duties. But now the editor of the MEDICAL RECORD wants to enlighten us, both young and old, particularly the former, on the methods of shaping a doctor's career, financial and other. The former might be described by some doctor who got wealthy on the proceeds of his practice. Of that class I have known very few whose lives and successes it is worth while to imitate; these few were peculiarly gifted, well informed, industrious, honorable, and favorably circumstanced. There are others who have obtained the financial results of the pretender and charlatan, who should, if it were possible, be read out of the profession. They follow the methods of the advertiser and shark. Altogether, however, wealthy doctors are scarce, that is, such as have succeeded in accumulating money out of their honest savings, not to speak of those who were rich before they realized the necessity of following their taste which guided them into the profession of medicine instead of landing them in Wall Street, or in a business. How large or small the number of those is who, after having saved a little, lose it in Wall Street, I have no means of knowing. Those, however, of my young friends who have a tendency to submit to temptations may be informed that gambling is unprofitable, and "Wall Street" is a Danaid barrel.

What is a doctor's career? There are five thousand of us in New York, twenty-five times as many in our country. I know many of us are poor, many make a moderate living for themselves and their families, some accumulate a competency, very few are wealthy. Almost all of us are hard-working, and at least as intelligent as average people. The probability is that if we spent as much intelligent work and zeal in other directions we should score a greater pecuniary result. That is why we have reason to be proud of our calling which gives us more opportunity for useful or noble work than for gathering treasures. That earnest and thoughtful pride I have read on thousands of faces during my lifetime.

A doctor's career is not only that which is connected with the practice of his profession on the sick or ailing. His very position in his village or town, the respect he controls, the fame he conquers in his neighborhood, his county, State, or in the world, is a career dear to its possessor. It is not always true what I read in an old book, that the ancients tried to make medicine a science and failed, and the modern people tried to make it a trade and succeeded. Nor is it uniformly true that men and women look for the object of life in enjoyment. What does it mean, after all, to enjoy life? The egotism of many has often been self-sacrifice; to that class doctors are apt to belong. It is the "career" of thousands.

Most of us are engaged in practice. How did we succeed in gaining and holding the confidence of our patients? We are not equal in learning, skill, or character, in looks, or habits; and still you and I, and all, make a living. The best explanation is the fact that the public, our patients, are as different as we are. In our ranks we have the most astounding, and the queerest varieties of physical, moral, and intellectual features. Still, we all "get somewhere." A man with a minimum of knowledge which he uses more or less conscientiously, or the reverse, may be as successful in practice as you are. Still, that is no reason why you should envy his ignorance or his lack of conscience. Our ranks are filled with the young and the old. Some are good-looking, or ugly, or tall, or short. I know one whose rachitic legs would do honor to a neglected Irish lad, and who is very successful; and a short, kyphotic colleague who charms men and, what is still more important, women. Some are dancers, sports, golfers, horsemen, know bridge, are the première theater visitors. Some talk philosophy, music, gossip with or without quotations, or describe operations in ladies' circles. Others frequent funerals and churches, and have the specialty of being called out. Some are serious, or boisterous, or jovial; bearded, clean-shaven, perfumed with cologne—not frequently—or tobacco, which is frequent. Some have finger nails manicured, some with mourning rings. They all have their adherents. Some talk in plain language, some are refined. Said the knowing one to the lady: "And how is the psyche of the baby?" "O, thank you, Professor, fine; quite regular every morning." Most have correct habits. I have known those, however, who owed large family practices to their spirituous capacities; "you could judge how bright they would be if only sober."

Fifty years ago I was declared to be "no German Doctor"—Kein Deutscher Arzt"—because I did not join the second breakfast, the "Frühschoppen"; and my critics enjoyed confidence and lucrative practices.

Some succeed because they are optimistic; others because they are pessimistic in diagnosis and prognosis. There are those who become popular because they have their waiting room crowded and their telephone in an uproar, not to speak of those who fill their place with shining and noisy tools and call themselves specialists. Some are loud and imperious; some whisper with obsequious servility.

Some obtain practice because they have become married; there are those who rely on their bachelorship. I know one at least who told me smilingly that his large practice among rich people and mothers of families was due to his "being in the market."

As there are many roads that lead to Rome, so there are many modes, or methods, or characteristics, or peculiarities that gain favor in the eyes of the public. For me and you, the question is which of these I have outlined, and the number of which every one of my readers could increase, is the one we should select in our endeavor to be successful in our "career."

The partly sad, partly delightful ignorance of the public in regard to the estimation of the doctor's characteristics, knowledge, powers, or responsibilities renders his position quite difficult, mostly so because the dear public "knows it all," anyhow. In things beyond its ken it trusts its clergyman; in matters concerning property or legal rights it never questions the superiority of a lawyer; in things medical, however, your neighbor considers himself your equal, or better. That is why the doctor's "career," his success, and his standing are so frequently dependent on the ignorance and lack of judgment of his or somebody else's patients, or, as they flatter themselves, "patrons." That is why, on the other hand, very credulous people overrate your powers, and the powers of medical science and art, and suffer from the belief that a single prescription may relieve a lifelong sufferer of his ailments; but also why impossible things are expected of you. That is why you may be looked upon as a miracle worker and deified, or upbraided like a pickpocket, or scorned like a bad character. It is only fifty years ago that a woman made a tenement block lively by proclaiming me the murderer of her child. I was quite innocent; and a fortnight ago I received a letter in which a man told me that the information he received of my absence from the city was an untruth, and that if the question was one of money I was to inform him of my charges so that he could consider whether it was worth his while to let me "inspect and diagnose his child."

So it appears that the peace of my mind and the shape of my career should after all depend on things quite different from the appraisement of those who cannot or do not care to judge. These things are strict attendance to our work, conscientious fulfillment of our duties, improvement of our knowledge, and our methods, and consistency of our behavior. It is these that should shape our career.

What distinguishes a modern doctor from his predecessors more than anything else is diagnosis. The public has long begun to ask for it. Fifty years ago it was not demanded as it is to-day. The patient went to a doctor as he would to a Delphic oracle, took his dose, and was satisfied. Fortunately, that has changed, though it may be uncomfortable to have now and then to tell a patient that he has to wait a day or two before he can know accurately. Instantaneous diagnoses, those "by instinct" or "tact," are rare, should be rare, and are mostly the credulous beliefs of inferior pupils of superior masters. Such diagnoses belong to charlatans, not to conscientious doctors who think before they talk. Indeed, even ignorant people expect us to give them the time required for examination. The period of thirty patients an hour has passed, unless it be continued in our ill-regulated and unnecessarily overcrowded dispensaries, whose methods will not be improved until the race for annual numbers shall be stopped. I find that our patients understand the necessity of careful examination and do not object to undressing, to auscultation and percussion, and chemical tests. Our practice, our "career" improves with the reputation we establish for care and industry. It is particularly the first examination that I advise my younger friends to spend time on. Listen to—while directing—the tales of woe; inquire into heredity, habits, and temperament; make a urine examination and that of every viscus. You save time in future examinations by being very accurate and painstaking in the first. If you cannot give the necessary time, then let him return. But do not be slovenly, and do not give the impression of slovenliness or inattention. Give your diagnosis, though you be not asked for it, as far as permissible. I mean by that, do not impair his health and comfort and destroy his hope by using the words tabes, cancer, or consumption. There are other terms with which he will connect less fear or despair. He comes to us for being improved or healed; by cheering when you cannot cure, you enhance innervation, improve digestion, facilitate sleep, and prolong life.

Make your own diagnosis. In regard to the employment of laboratories, the practitioner is too generous or too indolent. The simplest examinations he has become habituated to refer to them. Urine examinations, which everybody may conduct personally in his own office, he leaves to one of the "laboratories" whose number has increased immoderately. Many of them are run on mere mercenary "principles." One of them was directed to examine a specimen of human milk, and when asked for the percentage of casein, mistaking it for cow's milk, coolly reported over the telephone, "4 per cent." A few days ago a colleague presented me with two "laboratory" reports of urine sent by two different men. The case was a very urgent and dangerous one—pulmonary edema, dropsy—the reports spoke of a few pus cells, no symptoms of nephritis were mentioned; it contained, however, much pus, many granular casts, and pus casts. The doctor was imposed upon and excluded pyelonephritis from his diagnosis. The correct examination took a few minutes only. Instead of making his own tests, with no loss of time, he allowed himself to be misguided, and endangered the life of his patient. Simple examination of the blood should be made in every practitioner's office. The modern practice of delegating your duty has various results: Loss of time, uncertainty of diagnosis, the habit of accepting the diagnosis at the hands of men who are no physicians but sometimes meretricious tradesmen; it imposes unnecessary expense upon the patient, and undermines the respect and confidence of the public whom the doctor himself teaches to rely on the assumed superiority of an outsider. After all, however, the practitioner complains of the lack of that very confidence on the part of the public, and of his own loss of practice and standing.

The laboratory specialist is not the only one to whom we general practitioners give way too readily and sacrifice our own interests and those of our patients. The specialist has many advantages in modern practice. If he had not, his own class would not be so numerous. Common experience should convince us that for many specialists it is not the eager search for profoundness that is the cause of their early, sometimes premature, specialization. It is true they should be excused for many shortcomings for two reasons: Firstly, because they may be

made of practical usefulness to your patients in case of necessity and may fill a real want; and, secondly, because they limit themselves to a sort of hermit life away from the richer existence of the progressive general practitioner, with his wider horizon and greater interests—which among the specialists only those enjoy who are prepared by unusual talents and exertions, by universal education, by continued study, and by previous general practice. I see no happiness or dignity in the condition of those who do not appear to know that in spite of a diploma they are no doctors. Still, some of them will act the parts of such. The general practitioner knows and complains that they invade "general practice," but abstains from performing duties which, while claimed by the specialist, are his own duties and responsibilities. Not everything is adenoids that is claimed for operation. A chronic nasal catarrh or pharyngitis responds to mild irrigations and to a 1 or 2 per cent. silver nitrate application, at your hands as well as under specialistic care. An external ear catarrh can be treated with cleanliness, boric acid, resorcin, or bismuth subgallate. An occasional puncture of the drum membrane does not require unusual skill. A urethral stricture not amenable to your own bougies and to your own cocaine is rare. An "appendicitis" need not always push the doctor aside and clamor for a specialist. A chronic parametritis responds to your iodide and warm applications and rest as well as under the treatment of your neighbor. Your bandage will relieve an enteroptosis like that of the stomach specialist. A child's eczema or a zoster requires no erudition or skill not accessible to you but to the dermatologist only. If that be so, or rather, as that is so, my good brother practitioner, why do you not employ them? If you refuse, do not complain of hard times and popular disrespect, and of the impression gaining ground that genuine doctors are scarce or useless except for serving as the agents of a specialist, either self-advertising or legitimate.

I could go on telling what in my opinion the general practitioner should be able and willing to do for his patients. My city friends forget what our country brethren do when called upon to perform tracheotomy, or herniotomy, or paracentesis. They tell us that they know the use of soap and carbolic acid, and corrosive sublimate, and boiling water, and clean finger nails as well as city folks. The modern country doctor is as modern as the modern city doctor; sometimes more so. His career is what it always was, just as broad, only more effective, with less apparatus and less paraphernalia.

Success and career for the young doctor (not only for him) depend a great deal on his prognosis, which is guided by his diagnosis and his humanity. A bad prognosis given to the patient himself makes him worse and may be the cause of your discharge; and hopelessness on the part of the family may create disorder in the sickroom. Moreover, things are not always so incurable as they were formerly; besides, the diagnosis may be faulty or incomplete. Some instances of the kind I have tried to detail in the March number of the *New York State Journal*. Experience in regard to dealing with the sick and his attendant will grow with time. Those will make the least mistakes who know most and have a warm heart. Optimism dictated by it, and bridled by knowledge, will prove preferable to the pessimism of the man who is easily frightened. I do not speak of those who are pessimistic on purpose with the idea of impressing the patient with the pretended gravity of his case and the extraordinary power of the attendant over life and death. There are doctors and doctors; some are physicians, some medical tradesmen.

When I was requested to write a few remarks on medicine as a career, I thought of the general practitioners as my audience. They form the vast majority of those who are counted in our catalogues and registers and those on whom at the present time the health of the people does, or ought to, depend. Of the careers in medicine I excluded those who do our research work, and the great specialists and famous teachers of all classes who make those of us who practice at the sick-beds of the nation more erudite, richer in methods, more efficient—in fact, better doctors. In that they have succeeded to a great extent. With modern methods the opportunities of the doctor improve, and the young doctor matures at an earlier age than formerly. I believe that when Zimmerman claimed the thirtieth year as the period in which a man should be a perfect doctor if he ever were to be one, he was mistaken at his time—one hundred and thirty years ago. But the young men of our times, taught more and better than their predecessors, even in our America with its defective clinical (bedside) instruction—should be competent physicians before turning gray or bald. With improved facilities of diagnosis, and the results of pharmacologic experimentation and better methods of observations, aided by instruments of precision, therapy has become more efficient. Physical remedies, such as cold and heat, compressed and rarified air, electricity, water, massage, and climate, are being more utilized than formerly. To say that they have "come to the front" is a pet expression which means a great deal to one, less to the other. They too have their fashions and are subject to changes. But what we have learned in connection with that subject is, among other things, that much can be done with very little. Those who never opened a window before they were compelled to do so, change their "climate" at home quite suddenly. Those who could not afford to go to "Carlsbad" or to "Marienbad" may learn that "Saratoga," provided they do not overeat in a five-dollar "American plan" hotel, or sulphate of sodium at home with regulated diet, prove first-class "spas." Massage need not be the mysterious remedy which it is made out to be by the "professionals," who succeed in giving one of your patients a powerful relapse of an old peritonitis, and keep the other as legitimate spoils. The hot air specialist may be substituted by a simple domestic apparatus, unless you prefer that your patient whom you sent for a merely local application of heat is impressively massaged and douched, and sweated, and bathed by the man who "understands his business," and never returns your patient, who is solemnly told he has been poisoned with drugs.

And drugs? When we are told gravely that no drug "should be given unless necessary" we agree, but may be permitted to ask "necessary" to whom—the patient, the druggist, or the doctor? If to the patient, give drugs by all means as long as there is an indication for them. If you are told you must not give a "placebo," you will have a right to ask what that means. We are told that suggestion is permissible and proper in instances. A "placebo" may mean a great deal for a patient when a mild remedy is wanted—either domestic or one that is prepared by the druggist. You are aware that we have learned to treat an individual man with his

ailment, and longings, and prejudices—not the technical name of the ailment. Leave the decision as to medicines, or no medicines, or placebos to the practitioner who knows man, and his sick individual man; and women, too. There are many diseases which are not cured by medicine but which give way to the doctor. He may be fortified or not, as the case may be, by a mild drug for which there is an indication of some kind; or by rest in or out of bed, and change of diet, or climate. At the present rate, however, at which we practitioners abstain from doing our own work, our whole work, and leave the principal parts of treatment to menial substitutes, our "career" is the digging of our own graves and that of the general practitioner.

THE ARMY MEDICAL SERVICE.

By EDWARD L. MUNSON, A.M., M.D.,
MAJOR, MEDICAL CORPS, U. S. ARMY.

The Medical Corps of the United States Army consists of one surgeon-general with the rank of brigadier general, fourteen colonels, twenty-four lieutenant-colonels, one hundred and five majors, and three hundred captains or first lieutenants with the rank, pay, and allowances of officers of corresponding grades in the cavalry arm of the service.

All vacancies in the Medical Corps are filled by appointment by the President to the grade of first lieutenant, after the applicant has passed a successful examination before an army medical examining board and has been recommended by the Surgeon-General. Permission to appear before the board is obtained by letter to the Adjutant General of the Army, Washington, D. C., which must be in the handwriting of the applicant, giving the date and place of his birth and the place and state of which he is a permanent resident, and enclosing certificates, based on personal acquaintance, from at least two reputable persons as to his citizenship, character, and habits. To supplement these credentials, a careful investigation of the character, habits, antecedents, morals, and standing in his community of the candidate is made, prior to and at the time of his preliminary examination, by correspondence and personal inquiry by the army medical officers serving on his examining board. No political influence in securing permission to appear as a candidate is either necessary or desired, as appointments are made solely on the basis of merit. The candidate must be a citizen of the United States, between twenty-two and thirty years of age and a graduate of a reputable medical school legally authorized to confer the degree of doctor of medicine, in evidence of which his diploma must be submitted to the board at the time of his preliminary examination. Hospital training and practical experience in the practice of medicine, surgery, and obstetrics are essential, and an applicant will be expected to present evidence that he has had at least one year's hospital experience, or the equivalent of this in practice, after graduation.

The examination consists of two parts—a preliminary examination and a final or qualifying examination, as hereafter described, with a course of instruction at the Army Medical School in Washington intervening.

The preliminary examinations are conducted by boards of medical officers convened for the purpose at various military posts throughout the country, to enable candidates to take these examinations with the least loss of time and expense of travel. The invitations specify attendance by the candidate on a convenient board. Questions are prepared and sent out from the surgeon-general's office, to secure uniformity, and the various boards convene simultaneously throughout the country.

The scope of the preliminary examination includes the (*a*) physical conditions, (*b*) general education, and (*c*) professional knowledge.

A thorough physical examination is first in order. This is necessary to ensure that the candidate is fully qualified to undergo the fatigue and hardships incident to field service, and to which the medical officer is exposed equally with all other officers. Such examination is also necessary to protect the retired list from being overburdened by those having physical defects, which would render them liable to an early breakdown and to become a charge upon the Government. Those who fall below sixty-four inches in height are not accepted; that a candidate should possess a well developed physique and a dignified carriage and presence is of course desirable. Each candidate is required to certify that he labors under no mental or physical infirmity which can interfere with the efficient performance of any duty which may be required. Errors of refraction, if vision is not below 20/40 in either eye, are not causes for rejection, provided they are not accompanied by ocular disease and are entirely corrected by suitable glasses.

With respect to the subject of general education, written examinations are held in mathematics (arithmetic, algebra, and plane geometry), geography, history (especially of the United States), general literature, Latin grammar, and the reading of easy Latin prose. English grammar, orthography, and composition are determined from the applicant's answers to his examination questions. This examination may be omitted, however, in the case of applicants holding diplomas or certificates from reputable literary or scientific colleges, normal or high schools, or of graduates of such medical schools as require an entrance examination satisfactory to the faculty of the Army Medical School.

The professional examination is covered by written examination in anatomy, physiology and histology, chemistry and physics, materia medica and therapeutics, surgery, practice of medicine, obstetrics, and gynecology.

All examination papers are forwarded by the local boards to Washington, where they are marked and candidates are graded. Applicants who attain a general average of not less than eighty per cent. in the preliminary examinations are appointed to the Medical Reserve Corps with the rank of first lieutenant and are ordered to the Army Medical School in Washington for instruction as candidates for admission to the permanent Medical Corps of the army. An applicant thus selected is required to make an agreement to accept a commission in the Medical Corps, if found qualified, and that he will serve at least five years thereafter, unless sooner discharged. Besides gratuitous instruction, candidates attending the Army Medical School receive travel allowances from their homes to Washington, the pay of their grade as first lieutenants, $2,000 per annum, and a money allowance for quarters amounting to $36 per month.

An applicant failing in one preliminary examination may be allowed another after the expiration of one year, but not a third. Withdrawal from an examination during its progress, except because of sickness, is regarded as a failure.

The course of instruction at the Army Medical School commences on October first and continues for eight months. It consists of lectures and practical work in subjects which receive only a relatively small amount of attention in the ordinary medical school, yet which are of vital importance in the work of the army medical officer. Among these may be mentioned general and military hygiene, military and tropical medicine, military and operative surgery, pathology and bacteriology, sanitary chemistry, *x*-ray work, ophthalmology and optometry, besides other subjects, important to the young medical officer in governing his various relations and functions toward other branches of the military service. During this course of instruction the candidates are held under military discipline, and their character, habits, and general deportment closely observed. If for any reason a candidate should be deemed undesirable or unsuited to the service he may at any time be honorably discharged by the President, on the recommendation of the surgeon-general. The final examination comprises the subjects taught in the school, and is preceded by a thorough physical examination.

Candidates who, in their final examination, receive a general average of eighty per cent. and upward will be given certificates of graduation at the school; and those whose aptitude, as determined by the faculty, is deemed satisfactory, and who in addition to their final examination, pass a successful clinical examination, will be selected for commission in the Medical Corps. Candidates claiming a knowledge of ancient or modern languages, higher mathematics, or scientific branches other than medical, may be given a special examination therein. The relative standing of the candidates thus finally selected for commissions is determined from the total points obtained in the preliminary, final, clinical, and special examinations, with a grading for aptitude for the military service. Candidates who fail at any time to receive commissions because of lack of vacancies at the time of graduating may receive them in the order of their standing as vacancies occur before the graduation of the next class, serving in the meantime under their commissions in the Medical Reserve Corps. This question of sufficient vacancies, however, is of no importance at the present time, as recent Congressional legislation makes it certain that all successful candidates will receive commissions for several years to come. With the recent increase in the Medical Corps, there are at present 85 vacancies.

This careful professional examination and appointment solely on the basis of merit, entirely irrespective of political considerations, lies at the foundation of the efficiency of the Army Medical Corps. That it has always existed in an effective form is shown by an act creating an army of the Second Provincial Congress of Massachusetts, dated May 8, 1775, when medical officers of regiments could be appointed only "provided they appear to be duly qualified on examination." That the examination thus required was not of a perfunctory nature may be gathered from the following extract of a journal of the time: "On the day appointed, the medical candidates, sixteen in number, were summoned before the board for examination. This business occupied about four hours: the subjects were anatomy, physiology, surgery, and medicine. * * * Six of our number were privately rejected as found disqualified. The examination was in a considerable degree close and severe, which occasioned not a little agitation in our ranks." Under the system of rigorous elimination of the unfit which has been unswervingly adhered to by the Army Medical Corps for one hundred and thirty-three years, it may fairly claim to be a corps d'elite—a claim borne out by the accomplishments of Benj. Rush, its first surgeon-general; of Beaumont, whose classical experiments established the physiology of digestion; of Reed and Carroll, whose work in yellow fever has done more for mankind than anything since the days of Jenner; and of a host of others, living and dead, whose names stand at the forefront of medical thought and progress in their day and generation. The work at the Army Medical School, while exacting, need not be feared by candidates of good ability and diligence.

After securing a commission in the Army Medical Corps, promotion in rank, which means also increase in pay and allowances, comes steadily and with reasonable rapidity. This is true, however, only if the medical officer continues to demonstrate those qualities of efficiency and fitness which secured his original appointment. After three years' service a lieutenant, on passing a satisfactory physical and mental examination, is promoted to the grade of captain. If he is found physically disqualified, from causes in line of duty and incident to the service, he is retired, as if promoted, on three-fourths of a captain's pay; if found otherwise deficient, his examination papers are submitted to a board of revision and, if the latter agrees with the unfavorable finding of the board of examination, the officer is granted a year's pay, is honorably discharged by the President, and becomes permanently separated from the army. Promotion to the grades of major, lieutenant-colonel and colonel is by seniority, but there is an examination for the grade of major and another for that of lieutenant colonel. In the case of that for major, the procedure is the same as that given above for promotion to the grade of captain. The mental examination for the grade of lieutenant-colonel differs from that of major in that the officer, if unsuccessful, is not dropped from the army list, but is re-examined after a year, and if then found to be mentally disqualified he is summarily placed on the retired list without promotion. These examinations, with their penalties for failure, serve as constant incentives to the maintenance of professional excellence and largely replace the stimulus of constant professional competition which obtains in civil life, but which is absent from the army through its system of promotion by seniority. Advancement to the grade of colonel takes place without further examination. The surgeon-general is selected by the President from among the officers of the corps, usually those of higher rank and greater experience.

Having outlined the qualifications required of successful candidates, a consideration of what recompensed the Government will make in return for these qualifications is in order. These may be grouped as follows:

1. *Tenure of Office.*—This is for life, subject to the maintenance of good conduct and proper professional efficiency. The chief source of anxiety to workers in salaried positions is thus removed.

2. *Sickness, Disability, and Old Age.*—Absence from duty on account of sickness involves no loss of pay. Medical officers are entitled to retirement at any time for disability incurred in line of duty;

on attaining the age of 64 years they are placed on the retired list by operation of law. Retired officers receive three-fourths of the pay of their grade, both salary and increase, at the time of their retirement.

This provision for sickness and disability and care in old age relieves the medical officer of much of the worry which falls to physicians in civil life, who must constantly keep in mind the necessity for saving part of their income to provide for the interruption of practice from sickness and an enfeebled old age, when work is no longer possible. The army medical officer is spared these financial uncertainties which are the destroyers of much of the sweetness of life. While he foregoes the chances of accumulating great wealth, he is assured of a sufficient income for comfortable support when old and broken.

Reduced to figures, the retired pay of a medical officer retired as colonel, for example, is $3,750 per annum, which would be equal to a 5 per cent. investment of $75,000, or a greater sum than the average physician in civil life would be able to amass in a long life of professional activity.

3. *Pay.*—To each rank is attached a fixed annual salary, payable in monthly installments, and this is increased by 10 per cent. for each period of five years' service until a maximum of 40 per cent. increase is attained. For certain stations outside the United States there is an additional increase of 10 per cent. while so serving. A medical officer entering as first lieutenant receives $2,000 per annum, or $166.66 monthly. At the end of three years he is promoted to the grade of captain and receives $2,400 a year. In two years more he completes his first five years' service and receives an increase of 10 per cent., making his pay $2,640 a year, or $220 per month. After ten years' service the pay would be $2,880 annually, or $240 per month. The pay attached to the rank of major is $3,000 per annum, which becomes $3,600 after ten years' service, $3,900 after fifteen years' service, and a final maximum of $4,000 after twenty years' service. The monthly pay of a lieutenant-colonel is $375, of a colonel $416.66, and of the surgeon-general $500. This pay is an assured income. It is not subject to discount for uncollectible bad debts, nor does it become speculative, as in civil life, with fluctuation in the amount and character of professional work done or with the occurrence of periods of financial stringency. The problem merely is to cut the coat according to the cloth. With his mind free from financial worry, the army medical officer is in a position to undertake his professional work, and to enjoy his pleasures, to best advantage.

4. *Allowances.*—Besides the pay proper, officers of the army are entitled to valuable allowances depending more or less upon rank. These allowances cover necessary items for which physicians in civil life pay roundly, and which cause the most serious drain upon their incomes. Officers are furnished quarters free. These are usually sightly, convenient, and modern. Where they are not furnished, the officer is paid a cash allowance on a basis of $12 per month for each official "room." A lieutenant has an allowance of three "rooms" and may thus receive $36 per month as an extra allowance; a major five rooms, or $60; a colonel seven, or $84 per month. A gratuitous allowance of heat and light, sufficient for all reasonable needs, is also furnished, or may be commuted in cash when public quarters are not available. This is worth anywhere from $10 to $50 per month according to the rank of the officer and the climate in which he is stationed. Quarters are now supplied with a considerable number of bulky articles of furniture, kitchenware, etc., which thereby saves their purchase by officers. All medical officers are furnished with gratuitous forage, stabling, and transportation for two horses. Medical officers below the grade of major are supplied with two horses and horse equipments at Government expense, but if they elect to purchase their own mount a special money allowance of $100 per year for one horse, or $150 for two, is made. When traveling on duty a medical officer receives mileage at the rate of 7 cents per mile, which will usually cover all expenses of the journey. On change of station the Government provides for the gratuitous packing, crating, and transportation of all books, papers, and professional instruments; and transports free a reasonable amount of household goods, in the case of a major, for example, 7,200 pounds. Groceries may be purchased from the commissary at wholesale cost prices. Medical books, publications, instruments, and appliances are most liberally furnished by the Government for the use of medical officers, who are thus relieved from one of the heavy expenses of civil medical practice.

5. *Death Benefit and Pension.*—In case of the death of a medical officer on the active list his widow or other heirs receive a death benefit of six months' pay, and are also eligible for pension under the general pension laws. In the case of the death of a major, the death benefit would be $2,000, and the pension $300 per annum, or the interest of $6,000 at 5 per cent.

6. *Leaves of Absence.*—A medical officer may be granted leave of absence at the rate of one month per year, which, if not used, may accumulate to a total of four months. While on such leave, the regular pay of the medical officer does not stop, as does the income of the physician in civil life while on a vacation. Beyond the maximum of four months, an officer may still be granted leave, but receives only half pay during absence in excess of four months. Absence by reason of sickness does not count as regular leave.

7. *Social Life.*—The social side of army life forms a most pleasant feature of military service. The army officers of the line and staff are largely graduates of West Point, are men of education, refinement, and ability and, as a whole, are gentlemen in the best sense of the word. The medical officer stands on the same official and social plane with them and naturally forms many close associations and companionships. In the civilian society of the communities in or near which the medical officer may serve, he will find that his commission as an officer gives ready social recognition, where the same man, as a civilian, would first be subjected to a long period of probation. Physicians in civil life are more than kind to their confreres in the army and go out of their way to show them every professional assistance and favor. Most officers are married and, except in time of war, are practically able to have their families with them everywhere.

8. *Travel.*—A fixed home is out of the question in the army, where all are subject to orders and must move about as the need of the service requires. Strong local affiliations therefore cannot be maintained, and military service necessarily means abrupt changes in life, associations, and surroundings. Wherever he goes, however, the medical officer will find some of his old army friends and will make many new ones. In a few years' service, the

medical officer sees much of the world in general, acquires a relatively intimate knowledge of his own country and its dependencies, and has a large acquaintance among people of affairs. All this is a valuable education and broadening influence, and quite different from the narrowing tendencies by which many physicians in civil life must inevitably be beset. To many, the frequent change of station and infinite variety of scene, associates, and surroundings is a great charm of military life.

9. *Professional Opportunity.*—This will appeal strongly to the earnest student, for medical officers are officially encouraged in every way to keep abreast of medical progress. Every post hospital has a good professional library, to which additions are constantly being made. In addition, about twenty-five different representative medical journals are purchased and so issued or circulated as to reach every medical officer. The library of the surgeon-general's office is the largest medical library in the world and contained on June 30, 1908, no less than 291,346 books, journals, theses, and pamphlets. All these are available for loan to medical officers on request. The Army Medical Museum, under the same roof with the library, contained on the above date 34,447 specimens relating to medical science. With the existing policy of concentrating troops near large cities, army medical officers have excellent opportunity to keep fully in touch with the professional practice of civilian physicians and surgeons. In addition, medical officers approaching their examination for the grade of major are specially assigned to duty as attending surgeons at military headquarters in large cities, so that for at least a year they have opportunity to familiarize themselves with the methods of the leading medical men, and to benefit from clinics, lectures, and society meetings.

No better opportunity of winning a name in medical science is afforded anywhere than in the Army Medical Corps. This does not include medicine in all its branches, for with a class of carefully selected young men affording the vast majority of patients, and the discharge for disability of cases unfitted for further service, the field of practice in such matters as obstetrics and gynecology, the chronic diseases, and the diseases of children and old age is naturally restricted, and in the usual course of events the medical officer will scarcely find sufficient practical experience to develop into a specialist along these lines. On the other hand, the opportunities for the study of preventive medicine, bacteriology, pathology, the various branches of chemistry, and certain classes of diseases, especially those peculiar to the tropics, can scarcely be equaled under the best facilities of civil life. The practice of medicine and surgery greatly varies in both quantity and character with station, climate, and the factor of peace or war. There is a good deal of operating for appendicitis and the radical cure of hernia, both of which appear to be favored by military conditions. During the twelve months ending June 30, 1908, there were 3,009 surgical operations performed on officers and enlisted men. Of this number 2,915 were reported as successful, 32 as unsuccessful, 41 as failures, and 21 were followed by death. In the last class of cases the result depended on grave injuries frequently complicated with infection of the original traumatism.

The field of experimental research is particularly attractive, and one in which professional reputation is achieved much more readily than in general practice. Besides the opportunity, the medical officer has the time and money to engage in such work. His military duties can be so systematized that he can accomplish the maximum of routine work in the minimum of time and thus have many hours which he can call his own. The use made of such spare time, in the army as in civil life, depends upon the individual. His special line of work may be interrupted from time to time through official necessity; but if persisted in, nothing is more certain than that excellent results will be obtained. As the medical officer is scarcely influenced by financial matters, he is not under the scientific disadvantage under which many civilian physicians labor—that of constantly being diverted from a chosen task by the necessity of bread winning. Any special apparatus, laboratory equipment, books, or other facilities are gladly furnished by the higher medico-military authorities to those who give promise of reflecting credit on their profession and corps. With such facilities and official encouragement, there is no professional problem to the solution of which the ambitious medical officer of the present and future may not reasonably aspire.

THE NAVAL MEDICAL SERVICE.

By SURGEON WILLIAM H. BELL,

U. S. NAVY.

It may be fairly conjectured that from the time conflict was first waged at sea there has been some sort of provision for the succor of both sick and wounded, particularly the latter, on ships of war. And these provisions have, by the very nature of events, developed toward better things—albeit not *pari passu* with the needs and possibilities of the profession as did the art of making war.

Medical men have had an active part on board vessels of war since the creation of our government and the establishment of a naval force. The beginning was humble and the development slow and not uninterrupted; but, through the various disheartening vicissitudes, representatives of the profession who had chosen the sea as the theater of their careers exhibited a self-sacrificing loyalty to humanitarian appeals and a dogged determination to win their legitimate position. A foreseen destiny was the only encouragement.

Though the early history of the medical service of the United States Navy is somewhat obscure and the records meager and scattered, it appears that the representatives of the medical profession who served the country at sea during the revolutionary period rendered splendid service, and that they reaped a rich surgical experience is amply testified by the reports of the naval engagements. During these times, it appears that medical men were engaged for a cruise and discharged upon its completion, and it was not until just prior to the War of 1812 that the medical corps had its practical inception in the establishment of a permanent list of medical officers. Finally, in 1842, it became a component branch in the organization of the Navy Department, at which time the Bureau system was inaugurated and the corps was dignified by the appointment of one of its number as chief. Since the first appointment, up to and including the present incumbent, Presley M. Rixey, seventeen members of the corps have succeeded to the office, and during this time, in spite of many obstacles of one sort or another, the naval medical service has developed

under the guidance of a high ideal and the inspiration that an important field of work was open to it. Congress has been liberal in providing for its needs at different times, and the various surgeons-general have exhibited marked energy and ability in furthering its organization; but it is in the last six or seven years that the most noteworthy improvements and advances have been accomplished, and, to-day, the high standing and fine organization of the corps is due to the untiring efforts of the present surgeon-general and the interest and enthusiasm with which he has inspired those under him, so that the status of the medical officer of the Navy and his relation to other branches of the service is established on a high plane and he fills a position socially, professionally, and officially commensurate with the dignity of the medical profession.

At the present time the medical corps of the Navy consists of a surgeon-general, chief of the Bureau of Medicine and Surgery, with the rank of rear admiral (corresponding to major-general of the Army); fifteen medical directors, with the rank of captain (corresponding to colonel); fifteen medical inspectors, with the rank of commander (corresponding to lieutenant-colonel); eighty-seven surgeons, with the rank of lieutenant-commander (corresponding to major); ninety-six passed assistant surgeons, with the rank of lieutenant (corresponding to captain in the Army); eighty-nine assistant surgeons, with the rank of lieutenant, junior grade (corresponding to first lieutenant of the Army), and six acting assistant surgeons, who have the same relative rank as the regular assistant surgeons. In the grade of assistant surgeon there are approximately fifty vacancies, and in the grade of acting assistant, nineteen. This practically assures every successful candidate an immediate appointment upon passing the examination.

Graduates in medicine enter the Medical Corps of the Navy as acting assistant surgeons, and an applicant for examination and appointment as acting assistant surgeon must be a citizen of the United States, between twenty-one and twenty-eight years of age, and must apply to the Secretary of the Navy for permission to appear for examination. Forms for this purpose may be obtained upon application to the Bureau of Medicine and Surgery. If the preliminary requirements are satisfactory as regards age, citizenship, etc., the applicant may be given a permit to appear before the board situated at the place at which the applicant desires to be examined. Examining boards for the examination of candidates for appointment have been organized at the U. S. Naval Hospital, Chelsea, Mass.; the U. S. Naval Hospital, New York, N. Y.; the U. S. Naval Hospital, Philadelphia, Pa.; the U. S. Naval Medical School, Washington, D. C., and the U. S. Naval Hospital, Mare Island, Cal. Upon the receipt of a permit the candidate should communicate with the president of the board at the place designated, who will fix a date for his examination.

When a candidate presents himself for examination on the date so fixed, he must bring with him testimonials as to character and professional fitness, diplomas, and a certificate that he is a citizen of the United States. While it is not essential, it is desirable that he should have had hospital experience, or at least a year's practice in his profession.

The examination usually occupies about nine days, and is conducted in the following order: physical, professional, collateral. The physical examination is thorough, and the candidate is required to certify, on oath, that he is free from all mental, physical, and constitutional defects. Acuteness of vision, 12/20 for each eye, unaided by glasses, but capable of correction, by aid of lenses to 20/20 is obligatory. Color perception must be normal and the teeth good. If the candidate is found to be physically disqualified his examination is concluded; if found to be physically qualified his professional examination begins. This embraces two written questions in anatomy, one in physiology, two in surgery, two in medicine, one in pathology, one in obstetrics, one in medical jurisprudence, two in materia medica and physiological action of drugs, one in chemistry, one in clinical microscopy, one in hygiene, one in quarantine, bandaging, tourniquets, four operations on cadaver; clinical cases (a written report being made in one case giving history, diagnosis, prognosis, treatment, one prescription, at least, being written out in full, in Latin), uranalysis (chemical and microscopical examination of one specimen of urine), practical microscopy and recognition of five mounted specimens (histological, pathological, and bacteriological), and recognition of surgical instruments.

The written examination is followed by an oral examination in each branch, and the percentage is made up from the combined results.

The collateral examination is on those subjects usually taught at high schools, and may be omitted in the case of applicants holding diplomas or certificates from reputable literary or scientific colleges, normal or high schools, or of graduates of medical schools which require an entrance examination satisfactory to the naval medical examining board.

After the entrance examination, if successful, the candidate is appointed an acting assistant surgeon and is ordered to duty at a naval hospital until the first day of October following his entrance to the corps, when he is ordered to the Naval Medical School at Washington for a period of six months. At the expiration of this tour of duty, the whole class is examined for the position of assistant surgeon; the standing of each in the class during the school term is taken into consideration and fixes his standing in relation to the officers of the corps for all times, so far as rank and pay is concerned. The only chance of the status of an officer being changed is by special act of Congress, or court martial.

Three years from the date of his commission as assistant surgeon an officer is entitled to promotion if found qualified physically, mentally, and morally. After this, promotion takes place as vacancies occur in the higher grades, and preliminary to every promotion there is a professional and physical examination to determine the fitness of the particular officer, the basic requirements of which are that the officer shall keep abreast with his profession in every essential line of its progress and with the changing conditions in service development.

On entering the naval service medical officers are credited with five years' service (in recognition of the fact that they have been at their own expense in preparing themselves for Government service) for the purpose of establishing their date of precedence as regards rank and for calculating their increase of pay for length of service as follows: For every five years' service the pay of officers is increased 10 per cent. though not to exceed 40 per cent.), calculated on the annual base pay of their grade, as shown in the following table; but the pay of medical director is limited to $5,000; that of

medical inspector to $4,500, and that of surgeon to $4,000.

The pay of the various grades of the medical corps can be best explained by the following table:

Rank and Length of Service	Pay per Annum on Shore	Pay per Annum at Sea	Allowances per Annum for Quarters*
Acting Assistant Surgeons	$1,400	$1,700	
Assistant Surgeons	2,200	2,420	$432
Passed Assistant Surgeons	2,640	2,940	576
After 5 years in the service	2,880	3,168	576
" 10 " " " "	3,120	3,432	576
Surgeons	3,600	3,960	720
After 10 years in the service	3,900	4,290	720
" 15 " " " "	4,000	4,400	720
Medical Inspectors, after 15 years in the service	4,500	4,950	864
Medical Directors, after 15 years in the service	5,000	5,500	1,008
Surgeon General	6,000	6,600	1,152

When an officer goes to sea or leaves the continental limits of the United States under assignment to stations or for the performance of other duties beyond the seas, his pay is increased 10 per cent., and this increase is calculated upon the pay, including increases for length of service, which said officer may be receiving at the time of entering upon such duty or to which he may succeed by virtue of promotion or length of service during the performance of such duty, as shown in the above table. This increase for sea duty or service beyond the continental limits of the United States does not fall under the statutory restrictions above mentioned, which control the increase of pay for length of service in the grades above passed assistant surgeon, and the operation of this benefit is shown in the second column of the above table.

The attractive feature of naval service, as regards remuneration, is that pay is forthcoming with absolute certainty and regularity, while in civil practice the season, the number of patients, the character of the case and its duration, together with a varying discount in collection, determine the income, and this must always be a vacillating amount and a matter of more or less anxiety. Of course, in the service, if favorably stationed, there is opportunity to supplement the income from the Government by outside practice, and many naval surgeons add materially to their income in this way. Furthermore, a commission in the Navy is a life position, during good behavior, and pay continues whether on duty or sick, or on the thirty days' leave to which officers are entitled each year when their services can be spared.

All commissioned officers of the Navy, including the medical corps, are retired from active service at the age of sixty-two years, and when so retired, or when retired on account of disability incurred in line of duty before that age, receive an annual pay for life amounting to three-fourths of the highest pay of their grade at time of retirement. Recent legislation has made provision whereby an officer may be, on his own application and in the discretion of the President of the United States, retired after thirty years' service, with three-fourths of the pay of his grade at the time of retirement. In addition, provision was made whereby the widow, or any other person designated by an officer or enlisted man, will receive six months' pay, minus a nominal deduction for funeral expenses, upon death while on the active list from disease or injury received in the line of duty. This is, in itself, practically a substantial life insurance. When traveling under orders in the United States, an officer is entitled to eight cents per mile, and, when beyond the continental limits, liberal actual expenses, including tips, transportation of baggage, etc., consistent with the position of the officer, are allowed.

So much for the income. The expenses and cost of living of a naval officer, like those of a man in civil life, are about what his tastes and inclinations dictate. When ashore, he is provided with quarters or an allowance in lieu of them and may live with his family or mess with an officers' mess, in which the cost of living is always nominal. The same condition pertains to ship duty. The only mandatory expense is that of uniform, and here again an officer may be as extravagant or conservative as he desires. Upon entrance to the corps, an acting assistant surgeon is required to provide very little in the way of uniforms, and one hundred and twenty dollars will provide an outfit sufficiently complete for his needs until he is commissioned an assistant surgeon in the regular corps, when additional uniforms will be necessary at an outlay of approximately four hundred dollars.

Upon entering the Naval Medical School the young officer is put immediately into the atmosphere and environment of the service, and he goes on board ship, in this respect certainly, a more finished product. Aside from the professional features which will be more fully described later, he is instructed in the discipline and customs of the service ashore and afloat, matters of uniform, the use of side arms—in short, everything that is necessary to a proper familiarity with both the professional and military sides of a naval medical officer's career. After the completion of this course, as before pointed out, examinations for admission to the regular corps are held, and to those who pass commissions as assistant surgeons are issued and the officers then usually begin their first cruise.

The naval service, by virtue of its world-wide intercourse, is, as John Paul Jones contended, essentially aristocratic, in that it requires the instincts and discernment and conduct of a gentleman in its officer personnel. As the officers of the Navy have entrée to the very best wherever they go, and come in contact with the most cultivated and interesting people of every nation, it is necessary that personal qualifications should enter into the determination of general suitability for the service. Moreover, the wide range in the character of their clientèle and responsibilities call for a high professional ability and a ready adaptability. They are charged with the care of the enlisted personnel and officers of the highest rank and their families, and they are called upon constantly for medical advice and treatment by people native to the country in which they are situated.

The charge of the financial interests connected with the running of the Medical Department of the Navy makes it necessary that they be men of strict integrity and capable of handling the intricate and complex organization which has marked its gradual development during an existence of over one hundred years.

The increase of the Navy and Marine Corps to 55,000 men, and the care of the large civilian population, employees at yards and stations, together with the care of entire communities, such as are met

*Both within and (on shore duty) beyond the continental limits of the United States, but only when quarters are not furnished by the Government. In addition, there are also liberal allowances for fuel and light when on shore at home and beyond the continental limits of the United States, the amount varying according to rank, season, and the latitude of the station at which the officer is serving.

within the Islands of Guam and other distant stations, places an enormous population under the care of the Navy medical officers. They are assigned to stations where there is not only the necessity for the care of diseases peculiar to the Navy and peculiar to men, but also for a knowledge of all the specialties in medicine, including diseases of women and children. They must be familiar not only with the diseases prevalent in the United States, but also those which are peculiar to foreign countries, particularly the tropics; they must be familiar with all the laboratory methods in connection with the detection of diseases, and be able to employ them accurately; and they must be familiar with all the quarantine regulations of their own and of foreign countries and the sociological, as well as the medical, aspects of all nations.

The foregoing may serve to indicate that the Navy offers a broad field of professional activity of a practical sort, and there are fine opportunities for original work and initiative in many meritorious and promising directions. There are plenty of problems, which are matters of distinctly medico-naval concern in the first instance, though of general scientific interest as well, to call in play the keenest observations and the nicest ability in investigation.

It is, of course, desirable that the highest type of young medical men will continue to be attracted to the Navy as a theater for their professional careers. It is a scientific service, and there is every reason why its position as such should continue to improve. There is abundant work for the energies of every one, including those of special bent, and as far as may be consistent with the demands of the service for general knowledge and general ability, medical officers are allowed and even encouraged to develop themselves highly in some one branch of medical science, just as original research is approved and facilitated. There are already many officers who have taken up and are pursuing special studies, as, for example, ophthalmology, bacteriology and pathology, tropical medicine, hygiene and sanitation, chemistry, and genitourinary diseases.

Now, as to the provisions which have been made and are being improved to equip officers for every detail of their responsibilities under modern professional and service conditions. Among these, the first and most important is the Naval Medical School, which was established in 1902 and has been since rapidly developed in every feature of equipment and instruction, until now it may be truthfully said to have taken its place among the best postgraduate schools, not only of this country, but of the world.

While theory is given the place it demands, the cardinal idea of the work of the school is to fit officers for their military duties and develop them under careful personal tutelage to their highest point of attainment for the most capable performance of their practical professional work. Medical colleges, even those which prescribe a four-year curriculum, are laboring under the disadvantages of too short a course. In this regard the Naval Medical School serves an especially important purpose. It gives that finishing touch to their training which brings their attainments within conscious control for practical application, not only in the care of those who fall stricken with disease or injury, but in the management of threatened epidemics and all medical and sanitary emergencies. The course at the Naval Medical School broadens their knowledge and practicable capabilities to include those special subjects which naval surgeons have need to know and those peculiar responsibilities which devolve upon them and constitute a most unremitting demand for professional alertness.

Tropical diseases have come to occupy a large place in naval medical experience. The nation's interests are so firmly fixed, and the naval surgeon's sphere of practice is so frequently placed in tropical latitudes that now, more than ever, he is called upon to diagnose and treat their contributions to human suffering, and the development and scope of this branch of medicine has reached such proportions that too much stress can scarcely be laid upon the special need that the naval surgeon be prepared in this important field of work.

The Bureau has for many years furnished medical libraries and periodicals to medical officers wherever stationed, and during the past year the whole system of supply and distribution was revised and made more comprehensive. In addition to the usual journals from the public press, which are thus being widely circulated throughout the service, one or two copies each of certain special foreign or home serial medical publications are subscribed for for the Naval Medical School and the Bureau, in order that the corps of instructors may be placed in possession of the latest information from all sources for the purpose of teaching, in the one case, and that the Bureau may be in the position to carry out one of the important purposes of the United States Naval Medical Bulletin in the other. These special journals are rarely, if ever, seen by the medical officers scattered throughout the service, and it would be impossible, on account of the expense involved, to place them within their reach. As a matter of fact, it would be unprofitable to do so; for, in this progressive age, it is entirely beyond the capabilities of any one man to read all the important medical literature. Yet, it is absolutely necessary to keep in touch with every advance, and the Bureau, therefore, undertakes to review the great bulk of original work which is currently reported and to prepare abstracts for publication in the quarterly Bulletin.

With these provisions which the Department has made to enable medical officers to keep abreast of the advances in the profession, the service has become more and more attractive, and to-day it is a rare occurrence when a medical officer resigns to again enter civil practice.

It is not intended to give the false impression that the naval service is unalloyed bliss. No walk of life can, in good faith, offer that. There is some unpleasant duty, of course. The unsettled life; the sea service alternating more or less regularly with shore duty, which entails periods of separation from one's family; and the likelihood of a certain time of service at foreign stations, all mean varying degrees of hardship, according to the disposition of the particular officer; but there is always the consoling thought that it cannot, and will not, last long, and, besides, however undesirable a duty may be, there is an unfailing something to one's advantage to be gotten out of it.

In any event it seems wise and appropriate at this time, when the medical schools of the country are sending young life into the medical profession, to invite consideration of these facts which ought to be, and no doubt will be, of practical assistance in the solution of that ever-perplexing problem which comes to every doctor on the threshold of his career—the question as to what the next step

is to be, what the world offers for the exercise of professional attainments, and where opportunities for reasonably lucrative practice are to be found. In this strenuous age, marked by overcrowded professions, it is unintelligent to take a narrow outlook upon life, to fixedly contemplate one channel of activity as the only desirable and available one, to ignore the breadth of possibilities in the government service.

THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE.

By M. J. ROSENAU, M.D.

DIRECTOR OF THE HYGIENIC LABORATORY, PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE.

It is the ambition of thoughtful men to be occupied with the work they love, to have an opportunity of spending their leisure hours with the pastimes they prefer, and to have the privilege of enjoying the repose of peace and quiet in the evenings of their days. Those whose philosophy of life tends in these directions and who are satisfied with a modest competence, free from the worries and cares of commercialism, cannot do better than select a position in one of the medical departments of the Government service.

The question is sometimes asked us why we remain the servants of the Government when we might be independent in private practice. The answer is plain: The private practitioner is very many more times bound to the beck and call of his clientèle with less freedom and chance of relaxation than the "Government servant." The trite saying that "few die and none resign" has become an axiom in the Government service and well illustrates the contentment and calm which usually prevails in official circles. It means that many men of different temperaments from all sections of the country are satisfied with the life and work of a medical officer of our Government. While such a position offers some advantages over the cares and strife of the active practitioner, it is not without its responsibilities and disadvantages.

Having been requested to give a short exposition of the opportunities for making a living in the Public Health and Marine-Hospital Service that are open to the recent graduate in medicine, I will briefly state the requirements and kind of examination for admission to the service, the nature of the routine work required of its officers, their pay, and their opportunities for preferment; also, what offers in the way of travel, of pleasant companionship, and the winning of a name in science.

First, let me tell what the Public Health and Marine-Hospital Service is:

This service receives the first part of its long name from the fact that it has many public health duties to discharge, particularly the conduct of maritime quarantine, the management and suppression of epidemics, the medical inspection of immigrants, the maintenance of a hygienic laboratory in Washington, the Federal control of interstate traffic in serums and vaccines, the investigation of sanitary problems, and many other matters affecting the national health. It was formerly called the "Marine-Hospital Service," from the fact that it has charge of the marine hospitals which are located at our principal ports for the treatment of sick and disabled seamen of the merchant marine.

The Public Health and Marine-Hospital Service is a bureau under the Treasury Department in charge at present of Surgeon-General Walter Wyman, with a staff of assistant surgeons-general who are entrusted with the management of its various division details. Marine hospitals existed in the early days of our country under charters granted by King George III, but the service properly dates from July 16, 1798, when Congress passed an act for sick and disabled seamen, creating a fund for this purpose designated as the "Marine-Hospital Fund." The benfits of these hospitals were extended to sailors in the United States Navy until 1811, when Congress authorized separate naval hospitals.

In 1871 the service was reorganized and the position of supervising surgeon-general created, after which the Marine-Hospital Service rapidly outgrew its name; for, in addition to conducting marine hospitals, Congress from time to time imposed upon it additional duties and responsibilities, and its activities were so extended and its functions so multiplied that its work soon resembled that of a national board of health.

Therefore, in 1902, Congress gave the service its present name, the "Public Health and Marine-Hospital Service of the United States," at the same time further adding to its duties and responsibilities.

Advantages of the Service.—A service such as this, consisting of 131 commissioned medical officers, is like a large official family. The prolonged and intimate relationship between the officers of the service engenders the strongest ties of friendship, while the pleasant companionship and many social advantages which a life in the service offers add much to the pleasure of life. The discipline in the Public Health and Marine-Hospital Service is quasi-military in character, but while weekly inspections are had at each station, there are no tedious drills, and no time is wasted with routine exercises of a non-professional character.

Officers while on duty are required to wear the uniform prescribed by the President.

The particular advantage offered by this corps to graduates in medicine is that it is strictly a medical service. More than 50,000 sick and disabled seamen of the merchant marine are treated annually. Of this number over 12,000 are cared for in the twenty-two hospitals of the service. The service reports show that over 1,500 important surgical operations requiring the use of an anesthetic are performed annually. Not only is good opportunity offered by this large clinic to study all branches of the art and science of medicine and surgery, but the class of cases treated offers special opportunity for the study of rare and exotic diseases. Deep-water mariners bring strange and unusual parasites from all corners of the globe. Tropical diseases unknown in our climate may be found in all the seacoast hospitals of the service, affording abundant material for original scientific research. The new hospital at Ellis Island, where thousands of immigrants arrive each year, is in charge of officers of the Public Health and Marine-Hospital Service. The service in this hospital is probably the most unique of any in the world. Here are collected strange diseases of strange people from strange lands.

In addition to the medical and surgical opportunities offered by the service, an officer has abundant occasion to exercise his administrative and executive abilities. Each station, whether hospital or quarantine station, is in command of a medical officer, which is a privilege few appreciate excepting

those who have been hampered in their professional work by being subordinated to laymen.

Opportunities.—The various divisions of the service are in charge of older officers detailed (in Washington) as assistant surgeons-general, who have executive responsibilities of a high and difficult character, being responsible for the proper and economical conduct of the divisions entrusted to them. The service, as indicated by the first part of its name, performs public health work of a most varied and important character. It has waged many contests against yellow fever, and is constantly at warfare at the various quarantine stations along the gulf and South Atlantic coasts to prevent this dread scourge entering our country. This kind of work has given officers of the service the opportunity of winning enviable reputations as sanitarians.

The Public Health and Marine Hospital Service also conducts a sanatorium for consumptives at Fort Stanton, in the high and dry climate of New Mexico.

In compliance with the Interstate Quarantine Regulations it has taken an active part in preventing the spread of plague and cholera, in addition to yellow fever, whenever these diseases have become a menace.

Opportunities are afforded to the corps to promote the sanitary sciences, either at the Hygienic Laboratory in Washington or by original investigation at the various quarantine stations and hospitals of the service, some of which are equipped with facilities for laboratory work.

In order to prepare officers for the peculiar duties which confront them in the service, the younger officers of the corps are detailed to the Hygienic Laboratory at Washington in order to take a systematic post-graduate course in pathology, bacteriology, and various branches of the sanitary sciences that are not usually included in the medical curriculum.

From time to time officers of the service who show special aptitude for such work are detailed as special commissioners to study the cause and mode of transmission of diseases which menace the public health. In recent years there has been a leprosy commission, several yellow fever commissions (one at Havana, two at Vera Cruz, and one in New Orleans), while officers of the service have been on numerous occasions detailed to study plague, cholera, malaria, smallpox, "spotted fever," milk sickness, and outbreaks of other strange and unusual diseases which appear from time to time.

Requirements and Entrance Examinations.—To enter the service a candidate must be an American citizen; if of foreign birth, he must furnish proof of citizenship. The age of the applicant must not be less than twenty-two nor more than thirty years. He must be a graduate in medicine of some reputable college, and must pass a satisfactory physical, academic, and professional examination before a board of three commissioned medical officers. The board of officers detailed for the purpose of examining applicants for appointment is convened from time to time as vacancies or the exigencies of the service require. The board usually meets in Washington in the spring of the year.

Examinations are both written and oral and are always preceded by a very thorough physical examination. This is followed by an oral quiz on academic subjects, particularly to ascertain the proficiency of the candidate in general literature, the languages, history, geography, and the natural sciences, such as chemistry, biology, and physics. The written examination of applicants for appointment begins with a short autobiography, in which the candidate states his age and place of birth, schools or college at which he received his general and medical education, the general branches studied, including his knowledge of general literature and the ancient and modern languages, the opportunities he has had of engaging in the practice of medicine, surgery, or obstetrics, or of receiving special instruction, and whether he has been a resident physician or interne in a civil or military hospital, and the number of cadavers or parts of cadavers he has dissected while at college or elsewhere. The remainder of the written examination consists of questions in each of the following medical subjects: (1) Anatomy, (2) physiology, (3) chemistry, (4) materia medica, (5) practice of medicine, (6) practice of surgery, (7) obstetrics and diseases of women, (8) hygiene, (9) pathology and bacteriology, and (10) reports on special cases at the hospital.

Whenever it is possible applicants for appointment are required to perform operations on a cadaver, to show their skill in bandaging, and to demonstrate their proficiency in the technique of clinical laboratory work. An average grade of 80 per cent. is required. An applicant for appointment failing at one examination may be allowed a second examination after one year, provided he has not passed the limit of age above mentioned; but he is not allowed a third examination.

Pay and Emoluments.—After entering the service the candidate is commissioned by the President, by and with the advice and consent of the Senate, as an assistant surgeon with compensation of $1,600 per annum. After four years of satisfactory service he is examined for promotion to the grade of passed assistant surgeon with compensation of $2,000 per annum. Passed assistant surgeons must wait for a vacancy in the list of surgeons, to which grade they are admitted only after examination. Surgeons receive $2,500 per year. Six of the older officers of the service are detailed to the Bureau at Washington with the rank of assistant surgeon-general and pay of $2,900 per year. The surgeon-general receives $5,000 a year.

In addition to the pay above stated, officers of the service above the rank of assistant surgeon receive 10 per cent. increase of their annual salary after each five years of service. This increase is called a "fogy," or longevity pay, and officers are entitled to four such fogies after twenty years of continuous service. Commissioned officers of the service are also entitled to quarters, fuel, and lighting. Comfortably furnished quarters are provided at almost all of the hospital and quarantine stations; where no quarters are provided officers receive commutation at the following monthly rates: Surgeons, $50 at home and $90 abroad; passed assistant surgeons, $40 at home and $85 abroad; assistant surgeons, $30 at home and $80 abroad. Foreign commutation applies to any station situated beyond the geographical limits of the country as they existed January 1, 1908. This increased sum allowed for foreign commutation is in lieu of the increased compensation granted officers in the other arms of the Government service while in the Philippines and on other foreign details. Officers of the service and their families are also entitled to medical supplies. Thirty days leave of absence are allowed each year; leave of absence which is not taken accumulates until four months may be had with full pay.

Private practice is not regarded as inconsistent with the requirements of the regulations governing the service so long as such practice does not interfere with the proper performance of official duties. Officers stationed in remote places where skilled medical assistance is difficult to obtain are not infrequently consulted by citizens residing in the neighborhood. No fees are allowed for any professional, sanitary, or executive duties required by the regulations. Every inducement is offered to the officers of the service to publish the results of their investigations, whether of a clinical or a laboratory character, in the various bulletins and reports of the service or in medical journals, according to the circumstance of the case.

Publications of the Service.—The Service publishes a weekly journal entitled "Public Health Reports," containing information upon vital statistics and epidemiology, the progress of epidemics, and interesting data concerning quarantine, sanitation, and items of scientific interest.

The annual report of the Surgeon-General is a yearbook giving an account of the activities of the entire Service.

Special reports of the work done by officers of the Service are issued from time to time. Some of these are: A notable paper on pellagra in the United States by Lavinder; a comprehensive history of the recent pandemic of plague by Eager; authoritative papers on trachoma by Clark and Schereschewsky; a model plan of organization for the suppression of smallpox in communities not provided with an organized board of health by Wertenbaker; a résumé of the prophylaxis of tropical diseases by White; précis on the management of outbreaks of smallpox, diphtheria, and scarlet fever by Geddings; the prophylactic value of vaccination by Mathewson; a brief but complete history of federal and state action against tuberculosis in the United States by Kerr; an important contribution to the fourth (Filatow-Duke's) disease by Schereschewsky; three papers upon leprosy, embodying careful research work, by Brinckerhoff; original contributions to our knowledge of plague by McCoy and Wherry; the good results of treatment at the tuberculosis sanatorium at Fort Stanton, N. M., by Carrington; a review of the literature and further observations upon milk sickness by McCoy; particularly practical paper upon the etiology, symptoms and diagnosis of yellow fever by Goldberger; a timely article upon the prevention and destruction of mosquitos by Goldberger; a contribution to our knowledge of dengue fever by Goldberger and McCoy; useful articles on the trapping of rats and the management of a yellow fever campaign by Rucker; various reports showing the good work of the Philippine board of health by Heiser; observations on the life cycle of the yellow fever mosquito and the results of practical researches upon culicides by Francis; an account of the discovery of a new spirochete in yellow fever kidneys (*Spirochæte interrogans*) by Stimson; an exhaustive study of outbreaks of disease due to milk by Trask; the control of institutional outbreaks of diphtheria by Salmon; the results of the anemia commission of Porto Rico by Ashford (U. S. Army) and King; experimental studies of tuberculosis in market milk by Anderson; valuable essays upon uncinariasis by Stiles; and a number of other papers covering subjects of a public health nature.

Upwards of fifty bulletins have appeared embodying the results of researches at the Hygienic Laboratory. The Hygienic Laboratory of the Public Health and Marine-Hospital Service is located in Washington and comprises four divisions, viz., pathology and bacteriology, zoology, pharmacology, and chemistry. Bulletins of the laboratory have appeared upon the subjects of milk and its relation to the public health, investigations into typhoid fever in the District of Columbia and elsewhere, anaphylaxis, hookworm disease, antiseptics and germicides, spotted fever, the standardization of tetanus and diphtheria antitoxins; pharmacological investigations on digitalis, adrenalin, thyroid and other organo-therapeutic products upon ferments of the blood in health and disease; and other pathological, bacteriological, zoological, chemical, and pharmacological subjects.

A complete list of the publications of the Service may be had by applying to the Surgeon-General.

Seeing the World—One of the most pleasant experiences which comes to a medical officer is when he receives his first detail to represent the Government at a medical meeting. The Public Health and Marine-Hospital Service is always represented at important medical and sanitary gatherings, whether at home or abroad. These duties offer exceptional opportunities for keeping in the van of medical thought and of presenting in written papers the results of original observations and research.

Those who like to travel obtain a full meed of such enjoyment during the whole course of their official life. All officers of the service are subject to change of station. The regulations do not permit an officer to remain longer than four years at one place without being redetailed by the Secretary of the Treasury. The exigencies of the service constantly call for the services of experts familiar with epidemic diseases and sanitary problems, which involve much traveling back and forth. The hospitals and quarantine stations, as well as all contract and inspection stations, are regularly inspected in accordance with a definite plan. The service is also required by law to inspect, once each year, all establishments manufacturing viruses, serums, toxins, and analogous products. Boards of officers are convened in various parts of the country from time to time to examine candidates for promotion, to inspect sites for new camps or hospitals, to investigate the conduct of the service, and to perform miscellaneous duties and solve the many new problems that are constantly arising.

Actual traveling expenses and hotel bills, not to exceed $5 per day, are allowed medical officers while traveling under orders. This travel is frequently under the most pleasant circumstances and gives one an opportunity to see the world under advantages that can scarcely be appreciated by one not in the Government service.

The service now conducts both hospital and quarantine stations in Porto Rico, Hawaii, and the Philippine Islands, giving some of its officers the opportunity to take long sea voyages. At many foreign ports commissioned medical officers of the Service are detailed for duty in the office of the United States consul in order to sign bills of health and supervise the sanitation of vessels leaving for our shores. At present there are 3 officers in Japan stationed at Yokohama and Kobe; 3 in China at Shanghai, Amoy and Hongkong; 2 at Guayaquil, Ecuador; 6 in Canada, at Montreal, Winnipeg, St. John, Halifax, Victoria, and Lethbridge; 4 in Alaska, at Juneau, Nome, Valdez, and Ketchikan; 1 at Calcutta, India; 1 at Rio de Janeiro, Brazil; 4

in Naples, Italy; 5 in Cuba, at Havana, Santiago, Guantanamo, and Matanzas; 2 in Mexico, at Salina Cruz and Coatzacoalcos; and 8 in the fruit ports of Central America.

The medical officers of the Public Health and Marine-Hospital Service are given both time and opportunity for solving the great problems connected with the cause and prevention of disease. They enjoy exceptional opportunities for applying the sanitary sciences in the practical and useful work of keeping out exotic plagues, preventing the spread of epidemics, and scouring our fair land of its preventable scourges.

THE INSURANCE EXAMINER.

By HENRY H. SCHROEDER, M.D.,

NEW YORK,

MEDICAL DIRECTOR, MUTUAL LIFE INSUPANCE COMPANY OF NEW YORK.

The preparation of students for life insurance examining was not regarded as worthy of attention by our medical colleges until a few years ago, when a short and, in some instances, elementary course was included in the curriculum of a few of those institutions. The subject should be looked upon as a branch of medicine, and it is strange that its importance has not been more fully recognized, since the duties of the examiner are quite different from those which one is trained to perform in the capacity of family medical adviser. The position is also a very responsible one, even though it does not bring actual sickness or impending death into immediate consideration, for the life insurance companies depend largely upon the faithful and intelligent services of their examiners in protecting the interests of millions of beneficiaries—the wives and children of the policy-holders. The time has come when it should be made clear to those seeking the position that there is something more worthy of their reflection than the mere question of increased income, and that the possession of a high degree of mental equipment and moral tone is imperative if they intend to discharge conscientiously the serious obligations which they assume in the capacity of medical examiner. The object of this brief article is to give a general idea of the advantages and disadvantages which the position carries with it, and also the duties and qualifications expected.

Number of Examiners Required.—The field for the medical examiner extends everywhere, from the country cross-roads to the largest cities, as every village is supposed to have at least one examiner and large places more in proportion to their size. Each of the large companies has over 20,000 examiners in the United States alone, and the smaller concerns are represented by almost as large a number, as their agents solicit everywhere, though the total amount of business secured by them is not so great. Examiners often work for several companies, and in small places this is unavoidable, as there are not enough physicians available to give each company its own special representative. This practice is not confined to villages or small towns, as physicians are frequently met in larger places serving half a dozen different companies. It is, therefore, impossible to give even an approximate number of medical examiners in the United States, but it cannot be other than very large. There are companies that transact business in foreign countries where they usually select native physicians on account of their knowledge of the language and the people. It occasionally becomes necessary, however, to send some one abroad after he has received a special training at the home office; this is found advisable more especially in those countries where the principles of life insurance are not well understood either by the medical fraternity or by the public at large.

Applications.—If the company has a medical referee for the district in which the applicant lives, a request for appointment should be made to this official, whose duty it is to keep himself informed as to the standing and acquirements of physicians in his territory, or, at least, to have some means at his command for accurately ascertaining those particulars. If there is no referee, and the local manager of any company will gladly enlighten an applicant as to whether there is or not, correspondence should be directed to the home office.

The great majority of applications received by the companies are mere requests for appointments, and are not accompanied by endorsements of reliable and well-known persons or by satisfactory credentials. Such communications are filed, but when occasion arises for the selection of examiners in those localities the choice naturally falls upon others who have been found competent through information obtained by methods which the companies have at their command.

It is a general rule to refuse applications for appointments unless vacancies have occurred through suspension on account of incapacity or inefficiency, removal of examiners to other fields, or death. Any other policy would cheapen the position and give the present incumbents some degree of uneasiness as to the future demand for their services. There are times, however, when it becomes absolutely necessary to enlarge the existing staff on account of an increase of business or the discovery of some locality in which there is no examiner.

Medical men have been tempted to take out insurance, the agent having promised to secure their appointment as examiner as a reward, and having also led them to believe they would earn more than enough in the way of fees to pay the premiums. It must be admitted that a few companies have stamped this questionable procedure with their approval by making needless appointments in such instances, and that they were equally ready to repeat the performance as often as the agents could induce the neighboring physicians to play into their hands. *Verbum sat sapienti.*

Fees and Salaries.—Nearly $4,000,000 is distributed annually among the life-insurance examiners of this country. The individual's share of this vast sum varies, of course, according to the locality and size of the place that he has selected as a field for his practice. In villages it may not exceed $100, or even $50, a year. If, however, an energetic agent arrives in the neighborhood he may write insurance enough in a short time to bring in more than this to the local examiner as compensation for his services. In towns and small cities the examiner may expect to realize from several hundred to one thousand dollars. Here, again, the efforts of the agents must be taken into account, for it is only in the large cities that we are sure to find active and able solicitors at all times. In the large cities the earnings of examiners vary widely according to the company they represent, their rank, and the size and importance of the district to which they are assigned, and range from about $600 to about $2,500 a year. There are those who receive more by giv-

ing their time exclusively to this work, but it is questionable whether this is advisable or not, as they must depend upon several companies, none of which assure them permanent positions.

The largest companies have adopted the custom of paying their examiners by salary in most of the great cities, especially in New York City. In New York a Home Office examiner is started, as a rule, with a salary of $1,200, for which he is expected to devote at least two hours in the Home Office and to make several outside examinations, so that the amount of time given up by him is from four to six hours a day. During dull periods he is able to finish his work in less time, but he is always supposed to complete the work of the day, even in the occasional busy seasons, when it may take much longer. Examiners are always needed in the outlying districts of these large cities and, when on salary, receive about $600 a year. For this they make all the examinations within certain boundaries, but are not expected to go outside of their territory or to appear at the Home Office. The examiners at the Home Office, working directly under the supervision of the Medical Board, do not have as great a responsibility as those stationed in distant large cities where applications are also made daily for large amounts of insurance. It therefore becomes imperative to select men with long and wide experience at these points with remunerations in keeping with the high order of skill and care expected, the salaries in a few instances running as high as $3,000.

The fee system is retained by the small companies, as even in large cities the number of applications received by them for insurance does not warrant the payment of salaries; so there is an understanding by which the examiners receive the usual fee of $5 for each case and, in a few instances, report at the Home Office daily for a short time. As the corps of examiners consist of only a few men, an examinership in one of these companies is found to be satisfactorily remunerative.

It is possible to treat this subject of fees and salaries only in a general way, and these remarks must not be considered as referring to any one company. Each concern has its own rules and customs, which often differ radically from those of its competitors.

Advantages.—Some will probably conclude that the remuneration is not large enough to make it worth while, especially in small places. We can only say that during the intervals between examinations, one will have the consoling thought that he is really losing nothing, as no capital or expense has been demanded from him other than is actually indispensable to a general practitioner. Then again, the sum of $100 in a village where the cost of living is comparatively slight, is equivalent to several times that amount in towns or cities. There is also some benefit to be derived from the prestige and reputation that comes to a physician in whom a great corporation has shown its confidence and faith; this is especially true in small communities where everyone is more or less conversant with his neighbor's affairs.

Still another advantage which work of this kind gives is the examination of a healthy body occasionally; we all are aware of the importance of this practice for the purpose of keeping the faculties keen and well-balanced, but very few follow it up unless it comes in line with their regular work. The examiner also receives some mental training, too often needed, through requests from the Home Office to complete or revise unsatisfactory physical examinations and unfinished reports.

Whatever the income amounts to, it is sure to be paid promptly each month, whether the examiner recommends or rejects the risks, and there are none of the irritating delays in collecting that are unfortunately experienced in private practice. Salaries are paid monthly as a rule.

It has been our experience to find that a doctor is seldom too busy to accept an examinership, for he can make many examinations without consuming the whole or even a large part of his time. His private practice, which is naturally of most importance to him, will not be interfered with; it merely requires some method in the arrangement of his hours to do both kinds of work to the satisfaction of all concerned. It frequently happens that through making a more careful and painstaking examination than the applicant has been accustomed to, a closer intimacy is begun and a new patient added to the list.

Disadvantages.—There are no disadvantages to a conscientious and efficient examiner worthy of consideration, for the worst that can happen to him is the incurrence of the displeasure of the applicant or the agent when it becomes his unpleasant duty to advise rejection of the risk. No one is more vulnerable to the attacks of an enemy than the physician, especially in small communities, so it becomes a matter of self-preservation with him to avoid all controversies and unkind criticisms as far as he is able. A disgruntled agent or, worse, an angry applicant who thinks he has been treated unjustly, will on some rare occasion succeed in more or less injuring the reputation of an honorable and well-meaning doctor. The liability of this undesirable complication must be borne in mind when an application for an examinership is contemplated, for it has undeniably led to bitter animosities lasting for years, and even for life. Tactful management and good judgment will do much to prevent such strained relations. Then, again, the companies realizing the possibility of such a poor reward for services rendered in their favor, provide forms for confidential letters in which the examiner may freely give an expression of his opinion, though his regular medical report contains no unfavorable comment; these letters are sent directly to the Home Office and are looked upon as confidential. With this resource at his command, we feel free to state that when an unpleasantness arises, it begins with poor management on the part of the examiner.

Requirements.—Men who possess skill, education, and training are naturally selected whenever possible. The physician who has been graduated from a first-rate school of medicine, has seen several years of practice, has been an interne in some regular hospital, and is in good standing, will receive the preference. The country practitioner is not always able to meet all these requirements, and the selection must be made from the best obtainable. We wish to say, however, that with the exceptions that occur to every rule, the insurance companies have no more conscientious, painstaking, or faithful workers than the country examiners. In the larger places there is no difficulty in obtaining men who have all the qualifications desired.

During the past few years the large companies have adopted the admirable custom of training a necessarily limited number of men who have had a hospital experience. They remain at the Home Office for a period of from one to three months,

working under the supervision of the regular medical staff, and receive while there about $100 a month as compensation for their services. When the period of probation has ended they are given important posts at distant points. Only those are chosen for these positions who can furnish the very best credentials.

Generally speaking, those who possess the ability and temperament necessary to the making of a good family practitioner, will prove satisfactory as examiners. There are certain qualities that are so invariably found in the *ideal* examiner, however, that it will be well to specify them with the hope that they will be studied by the prospective applicant. In addition to a good professional education and standing, he must be a man of strict integrity and sobriety. The possession of a common-sense shrewdness in judging men's characters and lives, and the ability to estimate the value of past and present conditions from a practical standpoint, place him on a higher plane of usefulness than one who is a pure theorist. He is expected to be obliging in disposition and willing to make further investigation or examination on request from the Home Office, even though the fee does not compensate him for the extra services given in this individual case; in such instances he ought to find consolation in knowing that he usually receives very liberal payment for his work. He must feel that he has sound discretion and firmness in maintaining his position without giving offence or irritation.

Courtesy and power to maintain a calm state of mind on all occasions are most desirable qualities in an examiner, for there will be times, happily not often, when he will be subjected to annoyances and criticisms without just cause that will make it seem beyond his endurance to hold himself in; if, however, he loses control of his temper on such occasions, no matter how great the provocation, he also loses ground and sympathy; but if he maintains a courteous bearing and unruffled dignity, he has the best of the situation and keeps himself above the level of his opponents. While on this subject, we would once more call attention to the value of that great asset, tact; for we know of no position in which this quality conduces more to a good mutual undertsanding and peace of mind to all concerned than in the one under discussion. Examiners, most efficient in every other way, have brought down the wrath of the parties immediately interested and incurred the displeasure of their superior officers, all of which could have been easily avoided by the exercise of just a little bit of tact. The examiner should always bear in mind that he is serving others, the company and the agent, whose interests are much greater than his own, and for this reason should keep his own feelings in the background and ignore occasional slights and injustice. It should be his endeavor always, on parting from the applicant and the agent, to leave them good friends to himself and the company, even when it has been his unpleasant duty to give an opinion adverse to their interests.

Each applicant should feel confident that he will be able to fulfil these duties and requirements, as well as be ambitious to become an ideal examiner. His greatest reward will be his own consciousness of work well done, and the appreciation of those who are competent to estimate the worth of his achievement, compared with which fees and salaries sink into insignificance.

THE RAILWAY SURGICAL SERVICE.

By CLINTON B. HERRICK, M.D.,

TROY, N. Y.

ATTENDING SURGEON TROY HOSPITAL; SURGEON TO THE NEW YORK CENTRAL, THE RUTLAND, THE DELAWARE & HUDSON, AND THE BOSTON & MAINE RAILWAYS.

THERE is no public service more enormous in its proportion than the railway. The ramifications of the "iron highway" knows no border nor recognizes any limitation. Piercing every quarter of the globe, its trunk lines reach out sinewy fingers over prairie and sea, up and down mountain and canyon, its branches multiplying in ever-increasing ratio as the centers of industry and population are approached, and then a bewildering mass of glittering steel rails in the cities and terminals of both passenger and freight services. Add to this the street and suburban trolley lines that are rapidly increasing and stretching out so extensively, and, altogether the proposition reaches to a colossal degree.

Now, consider the fact that these railways have to be managed and operated by men, and plenty of them, and an army is at once established that is unequaled in numbers by any army in the world, reaching up into the millions. If we now add the number of passengers that are carried each year, and whose lives and limbs are in the custody of the operatives of the railway, while traveling upon them, no one can wonder at the necessity of a surgical service to assist in keeping this army well and free from injury, and to give aid and relief to them when they are sick or injured.

The Army and Navy have always provided a medical staff both in peace and war to govern the questions of health or incapacity of their corps, yet their sick and wounded are few in number compared with that met with in railway work, nor are the necessities for a medical corps in any wise more positive than for the railway army.

For some years the trunk lines of railway have recognized the factor as one of personal and general benefit, and staffs of surgeons have been organized along their lines. This example is being rapidly followed, and a surgical department established by all the large systems, that is becoming each year more important, both to the railway company and to the surgeon, and will shortly take its place among the recognized public medical services of prominence and authority. Not perhaps because the injuries received upon and by the railways are particularly characteristic has this subject become so prominent, but they are particularly severe, and also because, in the majority of the cases, cripples are made, nervous wrecks established, and a long battle between the professions of law and medicine frequently incited to decide the questions of truth or fallacy of conditions proclaimed.

The Requirements of a Railway Surgeon.—The railway surgeon needs be first of all a surgeon. His training should be theoretically classical, and his personal experience quite considerable and general. Bone injuries predominate, and in this he should be well skilled as to judgment and manipulation. He should be quick in action and conception, and steady in determination. In scenes of wreck he will be obliged to bring into play all the tact and skill he has in store to cope with the havoc and disaster. No one can imagine for an instant the great responsibility suddenly thrust upon a surgeon in a railway wreck, with the agonizing cries of the injured

the gloom or darkness of the surroundings, and the hysterical interfering crowds about the scene. To conduct the situation with consideration, propriety and skill to a satisfactory finish marks the man as a strategist of no mean degree.

The Staff.—A complete surgical service has a chief surgeon at its head who has entire charge of the department, assisted by division surgeons who have direction over certain sections, and in turn the local surgeons, who are appointed in each city or town of importance along the line, each of whom has a territory to cover, reaching in either direction to the next. Excepting the large railway systems in the West and South, none of the surgeons so appointed give their entire time to the service, but have private practice as well, and hold themselves always in readiness for a call by an official or employee of the road. While each surgeon has charge over his own district, no sharp lines are drawn, and he is expected to respond to any call near or far in case his aid is required. Reports are sent to the chief by the local surgeon of each accident as they occur, and monthly reports submitted with a summary of work done. This entails some clerical work on the part of each member of the staff, and if the corps is a large one the chief and his assistants have considerable to do in classifying and filing these. Frequently the law and claim departments are the recipients of these reports, either separately or in conjunction. On other lines of railways the surgical staff is under the immediate control and direction of the law or claim department, and no chief surgeon is appointed. Otherwise, the rules and regulations are much the same. In the larger systems, fully equipped hospitals have been established in their terminal cities and at points along the line, owned and operated by these companies, for the reception and care of its sick and injured. In other cases contracts are made with city hospitals to receive those sent by the company. As a rule, the railway surgeon takes charge of such cases, whether he is a member of the staff or not, as they are by the terms of the contract considered as private patients. In a few instances relief cars have been fitted up and equipped as rolling hospitals to carry the surgeons to the scene of accident and give every opportunity to care for the injured in the best possible manner, and this represents the highest type of an organized surgical department. On some systems the company hospitals receive both sick and injured employees, as well as injured passengers, and in some cases the families of the employee are as well entitled to the service. In these instances each employee, by reason of such, is a member of the Railway Relief Association and entitled to such privilege.

The duty of a railway surgeon is to be ready at all times and in all seasons with his complete surgical emergency outfit. At the least expected time he may be summoned, and then all else, either business or pleasure, must be immediately foregone that he may hasten to the relief of the injured. It may be he has to trudge or drive many miles to the scene of need, or, if his station is at a terminal city, a locomotive is frequently brought into service to hurry him to the case. He is given every consideration by the employees of the road to assist him and to follow out his instructions. He takes charge of the case and renders all the aid and relief he can to the individual, then arranges for his transportation to such a point as his judgment directs. It is his duty to accede as far as consistent to the desires of the individual or his family or friends, if they be near, but in this matter he is also to act on his own advice if the case appeals to him in any other manner. To the hospital is the rule of direction in all cases of severe injuries unless contraindications are preeminent; otherwise, to his home or other desired point. Besides giving attention to the individual and his injuries at the scene, he also takes notes of the surroundings in order to acquaint himself as far as possible with the matter of the cause of the accident and injuries, and other features, and includes these findings in the primary report. During the after care of the case reports are submitted as to the progress, and upon discharge a final summary. In this relation of railway surgeon and that of individual attending surgeon, both of which are at the same time being occupied, a peculiar situation exists, and the surgeon is expected to be deliberate but honest in his findings and reports. In times of "peace," the surgeon's duties take another phase. He is required to keep on hand his "kit" so that in the hurry of departure nothing will be forgotten. As to the contents of such, it is usually left to each one to select his own according to individual ideas, while some companies have a prescribed list of articles intended for first-aid service. He sees to it that packages of materials are kept in containers at the terminal stations, in roundhouses and yards, and in some cars, instructing the employees in their use and application. He posts cards of direction as to what the employees should do in case of accident. He assists in formulating rules for the proper care and fumigation of cars, and for the transportation of the sick and injured. He is required to examine applicants for positions on the railway, as well as those desiring promotion, as to their physical fitness for the duties of such position, and in this he is to pass only those fully up to the standard of perfect health and condition. Lastly, and by no means the least important, is the feature of examination of persons who are alleged to have received injuries upon the railway, in order that he may appear in court in support of his findings as to the actual conditions of disability or deformity. For all these reports and forms, printed blanks are furnished as a guide to the matters required, one of which is sent to the proper officer of the company, and copies filed by the surgeon making them for his own purpose.

Opportunity for Study and Experience.—One securing an appointment as a railway surgeon and making a study of its various phases will undoubtedly recognize many of the features that do not appeal to the surgeon unaccustomed to treating this class of injuries. In this wise he will find, as his work extends with the large variety of injuries to be met with, that he is given a school of the greatest value. He will meet many emergency cases and incidents that require quick perception and rapid action, this experience serving as a great teacher and proving a benefit to him in all the other phases of medical and surgical work that he meets from day to day. I believe that there is no class of surgeons so quick to act and to act so decidedly and well as those experienced in railway work.

The compensation of a railway surgeon varies. The systems that have a chief surgeon pay an annual salary to this official, and he is obliged to devote his entire time to the duties devolving upon him. Such assistants whose time is largely occupied in the service are also usually paid a salary.

Local surgeons subscribe to a "fee bill" and are paid accordingly for services rendered. The salary of chief surgeons may be of several thousand dollars per year, according to the extent of the service. Other railways pay their local surgeons a salary ranging from one hundred to three hundred dollars per year. Some pay for services rendered, without any stipulated "fee bill," such a sum for each case as is considered reasonable. In addition to the direct remuneration, the surgeons are given an annual pass over the division or entire line, and usually trip passes are granted to the dependent members of the surgeon's family. As extra fees the surgeon is paid for each examination in a medico-legal case: for examining prospective employees for service, and for appearance in court to give testimony.

How to Obtain an Appointment.—Appointments to the service are made by the chief surgeon, if such be at the head, or by the law and claim department, in either case it being approved by the executive officer of the company. Such appointees are selected with the view of obtaining the best general surgeon in the locality, and, where possible, one with a hospital connection. No examination is required, application being made direct to the appointing officer, with letters and documents from both professional men and laymen as to fitness and standing. The appointment is nominally for one year, but ordinarily lasts indefinitely.

The Advantages to the Surgeon.—Any office in the public service is reputable and worthy of seeking. If one is doing surgery, and especially if devoted to its practice, the appointment of railway surgeon not only stamps him a surgeon, but carries additional repute and distinction indicating that his skill and reputation are recognized by the corporation as of value, and worthy of their confidence in placing him in charge of their interests and in caring for those injured upon their railways. This prestige carries weight in every direction, brings one into contact with men of influence and position in the world, and is in every way worthy of acceptance. If such an appointee is not connected to an hospital staff, a strong influence is created which will probably secure him such association, as the relations between the hospital and the company are thus made more mutual and agreeable, and the connection regarded favorably by the hospital management.

The honorarium is not attractive, but, for the actual amount of work done during the year, it pays on an average a very fair stipend. The pass is a feature that appeals to many as a particular distinction, and the bit of pasteboard is a covetous possession, beyond the actual saving of traveling expenses during the year.

Disadvantages.—To one doing a general medical practice, any appointment to a surgical service of this importance draws from the public the inference that he is doing this work quite exclusively, and in time may work to his disadvantage in undoing his reputation as a purely medical man, and will be apt to cause him to lose many medical cases. For this reason such a practitioner should not accept the appointment, unless it be in the country towns where he is without much competition and the people accept the matter as one of propriety.

As to the chief surgency or appointments in which one's entire time is required to fill the position, there may be some disadvantages in being thus an employee without having the personal freedom that is a solace to the practitioner. Then, having no opportunity to do outside work, there is no chance to increase his income beyond the salary, which is rarely more than that attained by the successful practitioner after but a few years of regular work.

To the local surgeon there can be no particular disadvantage in holding such a position, unless it is that of the petty jealousy of some confrère for his having been selected for the service. This becomes more prominent when the company surgeon is directed to take charge of a patient who has been seen at first by some one else, by whom this transfer of the case is looked upon as in every way unethical, and who rarely stops from scoring the action as a robbery. The occurrence of these incidents is one of the most disagreeable matters of the service; and it has no justice whatever, as in these cases the railway pays the man giving first aid his fee for the same, and he should not expect to keep and treat the case.

Conclusion.—In comparison with other public medical services, or with the Army or Navy, that of railway surgery is not nearly so desirable. While the remuneration may be even greater, the tenure of office is more or less dependent upon the changes in railway management, or various other influences favoring a covetous competitor. Then, too, the dignity is not to be compared with that of a Government position, as at present the railway surgeon is looked upon largely as a necessary evil, and his relations, even with the company he represents, are not always pleasant.

His requests, and frequently his advices, are neither sought for nor heeded, and he is many times made to feel that his position is far from exalted. This is not universal, however, as may be noted from the high esteem in which many of our chief surgeons are held by their railway officials, and the confidence and close relationship existing between many local surgeons and their respective company. There is no doubt that the time is approaching of a still greater prominence of the service, its extension to every line of railway in the country, and the full confidence and respect granted it by the officials of the company, making the position of railway surgeon in every way worth the while of the most talented medical man to seek.

MEDICAL SERVICE IN THE MERCHANT MARINE.

By JAMES FRANCIS DONNELLY, M.D.,

NEW YORK

FORMERLY SURGEON IN THE TRANSATLANTIC SERVICE.

It has been well said that there is work enough for everybody on a ship, and the recent medical graduate or the landsman practitioner of riper years who turns to a sea life must quickly prove the truth of the statement. It is the purpose of this article to set down as clearly as possible the life of the medical man in the merchant and passenger steamship services, presenting its advantages and disadvantages. With pardonable pride in our national character, it may be stated that the American doctor has become known to the maritime world as being of the first rank. There are certain of the large steamship companies trading in all parts of the world whose home offices are abroad—addresses being given in detail further along in the article—who, with unfailing promptness, place American

doctors applying for positions as surgeons aboard their ships. In the passenger service to and from American ports, the native born and educated physician again has the advantage in the race for place over the foreign medical man for the reason that the various steamship companies, whether of foreign or native ownership, are now coming to recognize the fact that the greatest number by far of travelers back and forth from America to Europe who use their ships are Americans. A large source of revenue to passenger steamship companies is derived from shipping emigrants, and our government is becoming more and more exacting as to the qualifications in determining who shall and who shall not be permitted to take up residence on our shores. The American doctor again is by nature better fitted to appreciate the proper construction of the laws upon this subject and likewise to secure every advantage for the company which employs him to look after the medical interests of these would-be citizens and make the usual manifest notes regarding disease, which will aid the examining physician at Ellis Island.

Inducements.—The attractions drawing a young medical graduate, or the older practitioner, to the sea may be manifold. Besides an innate love for the ocean, personal health may be an attracting force. Sea life is probably more generally healthful than any other existence. More particularly in its sedative effects is it valuable to one who has undergone the lengthened strain of four or seven years—as when academic and professional courses are combined—in college. The older practitioner, after years of uphill effort, securing only moderate success, as well as the one who works an unrelaxing round, may, too, be attracted seaward. Educationally, a method of broadening one's scope—so essential to the physician—by travel and study of the many phases of human nature which are thus continuously presented to the ship surgeon, is offered.

Application.—Having decided to seek the position of doctor upon a vessel with the object either of working his way about the world or to secure the coveted berth of surgeon on a liner, the proper method of procedure for the candidate would be to secure an introduction to the general agent of the company upon whose ship he desires to serve. While personal influence has weight, a well-written letter stating the qualifications of the aspirant and the announcement that the doctor will call around himself within a few days to present his case in person, will prove of equal value. Persistence in the matter is a most important quality, and a weekly call upon the agent subsequently soon attracts that official's attention and gives notice that the doctor is still alive and awaiting his opportunity to serve the company in an official capacity. While awaiting the chance to secure a regular appointment the candidate should visit the various ships in port of the class in which he intends to sail, and become acquainted with ship doctors, who will be found a most approachable set of men. By this means he is not only learning his way about a vessel, as it were, but will often chance to meet a doctor desiring a substitute. These changes are quickly arranged, and the candidate, to take advantage of such opportunities, must be prepared to embark upon shortest notice. It is useless to write from a distance, as a personal interview is essential.

In the passenger service the American and Holland America lines employ American doctors almost exclusively upon their vessels. Other lines entering New York, particularly the German, are seriously considering the advisability of placing one or more American physicians upon their steamers. Freight steamers on call to a single port, or perhaps wending their way through many waters and visiting many countries before returning to the home port, which are known as "tramps," are sometimes more desirable as means of seeing the world. Probably the largest owners of steam vessels of this latter type are the "Elder Dempster S. S. Co.," sailing the Royal African Mail line of steamers, with general offices at No. 21 Water street, Liverpool, England, and the "Hamburg-American S. S. Co., Luisenhof, Hamburg, Germany, where applications may be sent.

Other vessels sailing from New York which sometimes or regularly carry American surgeons are the Hamburg-American, running to the West Indies, South and Central America; the Lamport & Holt, sailing to South American ports; Red D to Venezuela; Panama Line; Bermuda Line, and occasionally a foreign line, which may have a heavy passenger list, and which will then require an additional doctor of any nationality. Or, when a company like the Ward Line stops at an English port during a winter cruise, it must carry a surgeon, as the British Government demands that a surgeon should be on all passenger ships, otherwise they cannot clear the English port. This is an excellent rule, and the traveling public should demand a surgeon on other ships, at all times, for example, on those running between New York and Havana. It is nothing unusual to have 200 or 300 people on board during the busy season, and there are often quite a few cases requiring a surgeon's attendance.

Qualifications.—The personal qualifications of the individual who would be successful in his profession at sea are that, besides having a diploma from a reputable medical school of our country, he must be possessed of the manly quality of self-reliance, coupled with prudence in action. For he must remember that every doctor who enters a ship's company does so at a disadvantage. The popular idea afloat of the "ship doctor" is that being a failure ashore, he turns to the sea and would minister to jack-tar's ills. Government restriction in steamers of English registry running from England and between her colonies requires that the surgeon aboard must possess an English license if the combined number of crew and passengers is over one hundred persons. Dutch steamers have also government restrictions, but their enforcement is usually left to the steamship officials themselves.

Salary.—Payment for his services may be divided into two portions; first, the money received from the company as he stands listed upon the payroll, which includes his percentage from the sale of emigrant passage tickets. Second, the compensation derived from his patients, which may be truly termed the honorarium, as it may be in cash or a variety of articles. In the passenger service, the American and Holland-America lines pay the highest cash salary, which is fifty dollars a month; from thirty to fifty dollars being the limits in regular passenger service. In addition to this, the doctor may count upon receiving from twenty-five to two hundred dollars extra from various patients upon a good trip—financially considered—during the "season," which lasts from about the end of

May until July in the trips across from this side, and from the last of August up to October in the return passages. Besides money, the doctor is liable to receive anything which the recovered patient, returning home, believes might please the doctor. Or a monkey, a parrot, or a carved ship set sailing in a porter bottle by some old quartermaster, grateful but rheumatic, who does duty on the bridge, after having passed from a forty years' service before the mast of sailing vessels, may be received. In freight steamers the compensation is less. Of course, aboard this class of steamers passengers are few and far between, and extra money derived from outside sources is likewise scarce. Sometimes, however, the doctor may have a chance to secure extra fees by being called ashore to see a case in a port far removed from civilization; as in the case of wealthy native planters along the west coast of Africa, who pay for treatment in ivory, skins, or nugget gold, which may readily be converted into cash upon reaching home. Work upon the African trading steamers is hard but pleasant. The doctor is the captain's "chum" and is given greater opportunities to gain a knowledge of the language, life, and character of the natives than can be afforded in any other vessels. A few companies allow a wine credit of a certain amount per month for the use of the doctor when entertaining friends or passengers. The doctor's room and office is usually combined, but is of ample size in most instances. The living is the best obtainable in the large ships styled "ladies of the ocean," and in all there is a plentiful supply.

Disbursements.—The necessary expenditures at sea include the personal laundry account, although some companies allow the doctor's washing to be done at their shore laundry. The doctor is usually expected to pay for his table and bedroom steward service. As the one may be a grateful patient and the other be satisfied by a gift from time to time of the doctor's cast-off uniforms, the money expense need not be large. Extra wine and cigars are charged to the doctor's monthly account, which is kept at the company's general offices.

Outfit.—The doctor's personal outfit should include a dress uniform and a working uniform, with caps, with two or three sets of white duck uniforms for summer wear if the line of travel carries the steamer into torrid climates; a uniform overcoat; three sets of heavy underwear; six sets of light underwear; a dozen pair of socks, heavy and light; two dozen collars; a dozen shirts; a dozen handkerchiefs; cravats; three pairs of shoes; rubber overshoes; a pair of gum boots; storm coat (oilskin suit and sou'wester); toilet and shaving set; sewing bag (containing needles, scissors, buttons, thread). For professional work the doctor will require, besides a pocket surgical instrument case, the following instruments; hemostatic forceps (4); scissors (curved); dissecting forceps; splinter forceps; grooved director (eyed); probe; spoon curette; scalpel; curved (sharp-pointed) bistoury; hernia knife; soft rubber catheter (No. 10 French scale); needles (curved and straight); catgut and silk (sterile packages). He will need a good practical work on medicine to which he may turn in emergency and secure a rapid recollection of his knowledge of the diagnosis, pathology, treatment, and prognosis of the disease he has encountered; also a similarly adapted work upon surgery, for when he is most in need of the knowledge he requires he will have least time at his disposal to spend in reading up a chapter upon the subject. Books upon the specialties may be added to his working library for secondary reading, but the chief reliance will be found to be placed upon the emergency textbooks of the character which has been described.

Rank.—The official standing of the ship surgeon which is accorded by the company's standard is that of second in command to the captain, and of equal rank with the first officer. The standing which he obtains in verity is that which he makes for himself after coming on board. While the crew and officers generally will receive him with but illy concealed feelings of disfavor, he may ere long make them all his friends and devoted admirers, if when starting out, and ever afterward, he conducts himself with the grace and dignity which our calling demands in dealing with laymen. While in ordinary times the doctor aboard ship is expected to attend strictly to his own business, in times of crisis his judgment in many matters outside of his regular calling will be tested, and well will it be if he is able to stand the trials, as after a collision, or in time of fire.

Social Life.—As in society in general, social circles on steamships are made up of rather well-defined cliques. The captain is supreme in the little circle drawn from the passengers which he gathers about him. It has been said that the social atmosphere of a ship depends entirely upon the temperament of the captain, and this is true to the extent that his character affects those of his officers and crew directly and through them cannot but react to a degree upon the passengers.

The chief engineer and the first navigating officer form a set by themselves. The other officers make up still a third, while the doctor either "cliques by himself," or may gain an equal footing in all the rest. While the purser is the recognized police official of a steamship, it is to the doctor everyone goes in time of difficulty, whether arising among crew, passengers, or officers. Ship doctors may be called upon at times to decide with the captain the advisability, and to share in the responsibility, of placing a passenger, one of the crew, or an officer in confinement for misbehavior. Subsequent suits for damages are generally likely to follow such proceedings, and careful decision is required in these matters. The captain himself may, at times, be required to be subdued, as in a sudden attack of mania. The doctor in such cases must shoulder the entire responsibility for this restraining action. A carefully written statement corroborated by that of the crew, officers, and passengers would be required in such an event to protect the surgeon at the subsequent investigation by the company and the government.

Professional Relationship with the Crew.—The crew of a vessel are aboard of her for the object of working, and while the company provides medical attendance for those who are rendered incapable by accident or otherwise when pursuing the legitimate round of their duties, it expects the doctor not only to protect the interests of the crew against themselves, but to secure the best welfare and conduct of the ship by preventing individuals from taking advantage of this provision. The detection and prevention of malingering aboard ship is one of the surgeon's important duties. Alcoholic and venereal excesses are a common cause for disability among the men, and while the ordinary sailor has a childlike character in many respects, the doctor

must not show too great a weakness in condoning these offenses, which clearly destroy a man's power to work two or three days out from every trip. Such a man, for a time, may be able to make up his deficiencies to the company for his days of idleness, but soon he is being employed at a loss, and it becomes the doctor's duty in the matter to make this fact known to his superiors. A doctor allowing himself to become too sympathetic may easily cause disorganization of the entire crew upon his vessel.

Passengers.—In his dealings with the passengers the doctor naturally stands as the mediator between them and the company as represented by the ship's crew and officers. Avoiding discussions in all matters, fair judgment is required from him. While, after a few days out, the doctor may share the part with the captain of becoming a social lion, he must carefully avoid the appearance of becoming too popular. While he is the host for the nonce, he is still but the servant; his quickly-made friends will soon become forgetful of him, and if he would avoid discord he must prevent jealousy from arising in the breasts of his fellow-officers. A doctor who becomes a little abrupt during the extra bustle of changeable weather need not be surprised to find that the officials in the general office of the company have been notified by various tourists of his slights to the passengers. Ever mindful of the delicate position which he occupies, he will be required to exercise constantly all of his resources to cope with the arising situations. The surgeon may often serve his company and win their commendation by his power to prevent damage suits arising from accidents to passengers aboard his ship. With the exercise of a little tact a statement, which he may have in printed form, expressing satisfaction of the injured one or his friends with the treatment received will, after it has been signed, act as a deterrent when thoughts of securing legal redress arise in the minds of the patient or his family.

Steerage Passengers.—From time to time a magazine writer of more or less repute will travel "steerage" and upon his return set himself the task of recounting his experiences, finding little to praise and much to blame in the manner of handling the emigrants. As a matter of fact, emigrants to-day travel to our country in far greater safety and in much more comfortable quarters than did the country's forefathers. The comfort of the emigrants is further insured, on the Holland-America Line, by the fact that the captain, chief officers, and doctor all receive a percentage of the third-class passage receipts. The other lines might well imitate this policy for it is an incentive for better service.

Disputes must be adjusted and all disorder carefully repressed among the emigrants, for, in time of panic, their actions are the chief disturbing element aboard the ship. Sanitary measures must be instituted and carried out for the general good of the ship, and it is the doctor who is the chief organizer and executive officer in charge of these matters. His duties require that he make a careful examination of every emigrant passenger before he boards the ship for the purpose of detecting the unfit. The importance of this may be imagined, for if a single individual suffering from an incipient epidemic disease, such as scarlet fever, smallpox, measles, or yellow fever, were allowed to embark, the subsequent epidemic arising when at sea would cost the company many thousands of dollars' loss in quarantine expenses and fines, aside from the number of lives which might be sacrificed. Eye diseases are likewise of importance, as quarantine officers in the American ports are particularly charged to reject emigrants presenting chronic eye diseases, especially when of a trachomatous nature. As precautionary measures, candles and garlic are confiscated from the immigrants whenever found. A law of our government requires that all third-class passengers be vaccinated. This duty devolving upon the doctor, he finds it to his advantage to perform the work early in the voyage, else its performance becomes an almost utter impossibility, owing to seasickness, if the weather becomes at all rough. It is therefore not uncommon for a ship doctor upon one of the large transatlantic liners to vaccinate from seven hundred to one thousand five hundred steerage passengers during the first day out from the foreign port. The implement by which this is accomplished consists commonly of a handle fitted with an attachment similar to the lead-holding device in the ordinary indelible pencil. By this means sharp, pen-like stylets are held in position while being used upon the patient's arm. Several stewards are engaged in loading the handles. The point after being dipped in the virus, provided in a receptacle at the surgeon's side, and applied, is discarded. Infection from one person to another is thus avoided. Daily inspection of the scars is a part of the ordinance, but this is impossible owing to the press of other work. Stewards are therefore required to check off the necessary inspections at the final sea inspection of the surgeon, which takes place a day or so before sighting land. But little trouble is experienced in carrying out the government health regulations save with that class of returning emigrants who, having spent some time in America declaring for citizenship, are returning after a visit to the fatherland. These persons, who are known as "one paper men," often resist and stand upon their rights as citizens to claim exemption. Notice to them, however, that they will be denied a landing if they do not submit to the laws of the country of their adoption quickly brings acquiescence. In general, these people have to be treated with strictest discipline. Knowing no law but that of the military force of their country, emigrants are quick to take advantage of apparent weakness upon the part of the doctor in the pursuit of his duties among them.

All classes of passengers will seek information as to the daily health report of the ship during a voyage. The uniform reply to such questions, whether from a steerage or first-cless passenger of "All well aboard," will turn the questioner aside and quell the fears of the timid. Some steamship companies, when a death occurs from ordinary causes among the steerage passengers and which has been followed by burial at sea, tacitly expect the doctor to protect the corporation's interest by either making out a lax report or by omitting to mention the occurrence altogether in the papers to the quarantine officials. This saves time and money sometimes, but is perilous, for if the offense be detected, the company is not only heavily fined, but the doctor himself becomes henceforth a suspicious character to the officials.

Accounts.—The clerical work which the company and government regulations require from the doctor is such as relates naturally to his professional duties. His name must be attached to all official papers relating to the health of crew or passengers. His signature attached places him upon his honor as to the truth of the contents of such indentures.

Rejections of immigrant passengers at the port of embarkation with a statement of the cause must be officially noted by him. Sickness or death occurring among either crew or passengers must be also entered, accompanied by the doctor's descriptive statement.

Hospital Facilities.—The space accorded to the doctor in the treatment of the bedridden is limited to the patient's own berth in some steamers. Others have a special cabin or sick bay, far removed from the living quarters, where the sick may be isolated. Cabin passengers in time of epidemic are quarantined within their own staterooms. Steerage passengers, from whom most is to be feared, on such occasions are segregated so far as is possible in the necessarily limited space at command. Help from passing steamers may be secured in time of need according to the universal law of nations, whereby a transfer of patients may be effected or additional medical aid be obtained.

Supplies.—Modern steamers will be found equipped in most instances with an adequate supply of drugs, splints, dressings, and instruments suitable for emergency or routine use. Many companies give the doctor free scope in his ordering, and are willing to purchase the best in the market. Besides the usual salves, ointments, and plasters, many of the most important drugs of the pharmacopeia, put up in tablet or compact form, are provided. Instruments include a set of sounds, tourniquet, general operating, anesthetizing, obstetric forceps. The best medical journals published in our country are either subscribed for or sent gratuitously by the publishers to all of the ships upon the important lines.

Work.—An idea of the amount of work which may be crowded into the ship doctor's day of twenty-four hours may be obtained from the statement of a doctor aboard one of the crowded homecoming liners in the late summer of last year. This gentleman kept a partial account of one day's work during rough weather. He made a total of two hundred and eighteen visits to cabin passengers' staterooms in visiting patients, each one of which had to be seen to and treated with the same careful handling that the shore doctor employs. Office visits were not included in this computation. Besides the daily and nightly round of burns, scalds, and "cramp cases" occurring in the fire-room gangs, there are usually one or more individuals in the great company which a ship's crew musters who will require the doctor's continual attention. The populous steerage with its numerous progeny of children and mothers will demand a good share of the doctor's time, besides childbirth cases, averaging one or two in number every voyage during the season.

Seasickness, brought on most often by the overindulgence in eating and drinking of the last days before sailing, with its usual concomitant condition of constipated bowels, takes up an additional share of the surgeon's hours and calls for a goodly supply of patience, castor-oil, epsom salts, calomel, and compound cathartic pills in the treatment, the general specific ordered being "champagne for the first passengers, and beer for the steerage." Local treatment which, though homely, yet finds the greatest favor in the ship doctor's eyes is the application of the so-called "sea-belt," which consists of a beer bottle wrapped up in a towel and bound in position tightly over the region of the stomach.

Besides his rounds of day and night "calls" the doctor attends, with the captain and chief officers, the daily inspection of the ship when at sea. Landing of the immigrants must be overseered by the surgeon, and their transfer to the government landing station, and subsequent inspection and distribution are all a part of his regular duty.

Summary.—Advantages—By securing a position of surgeon aboard a steamship the young doctor will gain valuable experience in the study of human nature. He will be enabled to visit foreign countries and the different races of men. A week in each port, which is the usual stay of the great liners, will, however, prevent the surgeon from making extended trips from these ships. Probably six months or one year will suffice to enable the young medical graduate to gain a knowledge of sea-life as the doctor sees it. To the physician in search of health, if he be not too great an invalid, which would certainly handicap him for the activity of ship life, a valuable and inexpensive way is opened to enable one to secure a change of scene.

While the chance for social advancement may be easily overrated, the ship doctor is thrown in close contact and most pleasing intimacy with the most cultivated and highest types of our people, and the impressions which he makes will depend in great measure upon his demeanor and character.

Disadvantages.—The doctor aboard ship is considered an "idler," for while he may be oftentimes continuously engaged for hours or days he has periods of inactivity. The irregular life which is sometimes demanded is detrimental. There is a constant danger of contracting habits of intemperance in eating and drinking, with a tendency to avoid active exercise beyond that required by professional duties.

Unless upon his guard, the doctor will become weakened in moral stamina by the life at sea, and lose ambition to advance to the heights in his profession.

INSTITUTIONAL WORK FOR YOUNG PHYSICIANS.

By WILLIAM P. SPRATLING, M.D.,

BALTIMORE, MD.

PROFESSOR OF NERVOUS DISEASES, COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE, MD.; FORMERLY MEDICAL SUPERINTENDENT OF THE CRAIG COLONY FOR EPILEPTICS, SONYEA, N. Y.; MEMBER OF NEW YORK ACADEMY OF MEDICINE, AMERICAN NEUROLOGICAL ASSOCIATION, ETC.

It is estimated that about 10 per cent. of the recent graduates in medicine fail for one reason or another to take up private practice. Just why this is the case does not concern us at the present time; but I will say that in all probability the chief reason for it is found in the fact that so many young men in order to complete their medical education are compelled to borrow money for the purpose, and it is natural for them to seek a salaried position as soon as they are out of college that they may pay back the loan. We must also remember that the financial cost of acquiring a medical education has increased to a very marked extent during the past ten to fifteen years. Not only has there been a goodly increase in the amount of the college fees that are demanded, but there has been a corresponding increase in the cost of living. (Baltimore, which has a number of medical colleges, furnishes a fair illustration in this respect. In 1889, students were able to procure very good board and lodging for $4 a week. At the present time, $5.50 and $6 is demanded for the same accommodations.)

I will not attempt to give any accurate estimate of the number of positions in this country filled by young physicians whose services are rendered for a fixed salary. To name the character of some of them will be sufficient. Practically all States maintain a large number of asylums or hospitals for the care of their insane and for other defectives. A reasonable estimate would place the number of such institutions in the United States at not less than one hundred and sixty to one hundred and seventy-five; and assuming that each institution employs an average of five physicians on its staff, we have at once a total of 800 to 900 so employed. In addition to the physicians in these institutions, there are also others employed in reformatories, penitentiaries, hospitals for tuberculosis, for the care of epileptics, the blind, the idiotic, the feeble-minded, and others.

Large municipalities that have a population in excess of two hundred and fifty to three hundred thousand employ good large corps of physicians on boards of health, as public vaccinators; in the inspection of public school children for contagious diseases; as quarantine officers and assistants, and as inspectors for the offensive trades. Taking the entire aggregate of all salaried physicians, including those enumerated above and such others as are offered by steamship companies, by mining corporations, by railroads, in public laboratories and the like, and exclusively of medical officers in the Army, Navy and Marine Hospital Service, it is safe to say there are 1,200 to 1,500 salaried positions for young physicians in the United States, in which vacancies are occurring quite frequently.

We will take up the larger division first—those employed in the care of the insane, and since my knowledge of these particular institutions in New York State is better than it is concerning any other state, and for the further reason that there is a marked similarity in the character of this work throughout the United States, I will give some details of the New York State positions, how they are obtained, the pay, etc. Here all medical officers are under the civil service, and while much of a debatable character may be said concerning the value of this service, the final argument would be in its favor. I make this statement after a service of 15 years as the executive head of a large institution in New York State, and with an average of 10 assistants employed under my immediate supervision. I recall but one or two instances when the operations of the civil service law made it difficult to procure the particular physician wanted to fill some particular position. I invariably found the State civil service commission entirely willing to listen to suggestions concerning improvements in the methods of holding examinations for medical positions, and especially was this true in instances where special fitness was demanded, as in pathological or strictly scientific work.

Most physicians who enter this service enter the lowest grade—that of medical interne; a position, I believe, that is the same throughout all institutions in the United States. As a rule, medical internes must not be more than 26 to 28 years of age, unmarried; must have had not less than one year's practical experience in general hospital work; must be graduates of a regularly incorporated medical school, and must present testimonials vouching for good character, conduct, and the like. Examinations for medical interne are non-competitive and are held at the institution where the appointment is to be made. As a matter of fact, the appointing officer selects the individuals he desires to appoint, and then the examination is held; so that in this case at least a nomination for examination is substantially equivalent to an appointment.

The salary of the position is uniformly $600 a year with maintenance, which includes furnished quarters, board, laundry, postage, stationery—in short, all things necessary for living, with the exception of those that are strictly personal—such as clothing.

It is generally understood that medical internes will seek an examination for promotion at the end of a year's service to the next higher grade, which is that of junior assistant physician. Here competitive examinations are required, and they are simultaneously held in various cities of the State, the purpose being to make the examinations as attractive to as many candidates as possible. The questions for examination are prepared by physicians employed for the purpose, and it is proper to say just here that these examinations within my experience are eminently fair and just. They are usually completed within a single day, although when special topics are covered a second day is sometimes required. Junior assistant physicians are paid $900 to $1,200 a year, increasing from minimum to maximum at the rate of $100 per annum. The term of service in this position varies, and is determined by vacancies in the grades higher up.

The next examination is for the position of assistant physician, the pay of which begins at $1,200 and increases at the rate of $100 per annum until $1,500 is reached. The next grade above this that is examined for is that of second assistant physician, the pay of which begins at $1,600 per annum and increases $100 a year until the maximum of $2,000 is reached, at which figure it stands so long as the incumbent continues to hold it.

Next comes the position of first assistant physician, which corresponds to that of assistant medical superintendent. This position is one of great importance. The first assistant is by law the ranking officer in charge of the institution during the absence of the medical superintendent. His examination for appointment, therefore, embraces questions in administration which are not given to officers lower in the scale. The pay of the first assistant physician begins at $2,000 per annum and increases at the rate of $100 until the maximum of $2,500 is reached.

In all the foregoing, as well as in the case of medical internes, full maintenance is provided. First assistant physicians are also allowed maintenance for their families, and second assistant physicians may board their families in the institution when room is available. The charge for such board by the State is merely nominal, meeting only the actual cost.

The chief position in such institutions is that of medical superintendent. Candidates for this must be not less than 30 years of age, must have had five years' actual experience in institutional work, and must pass a competitive civil service examination, the questions of which are largely administrative, while many of them pertain to matters of sanitation and hygiene. Knowledge of hospital construction and organization is also required. The pay of medical superintendents begins at $3,500 a year and maintenance for the officer and his family, and increases at the rate of $100 per annum until the maximum of $4,500 is reached.

There is no fixed term of service for any of the

positions mentioned above. Appointment to them is made by a board of managers or trustees who have supervisory charge of the institutions, such boards being appointed by the Governor of the State, by and with the consent of the Senate. It is due the service to say that these positions are non-political; boards of managers serve without pay. In my fifteen years of continuous service I was never personally asked to make an appointment that was in any sense political, and I never made one of that character.

The sole cause for appointment is merit, and all worthy candidates have an equal chance. When it is found that an appointee is not meeting the demands placed upon him, that his work is not satisfactory, the appointing power has the right under the law to dispense with his services without formality if it be done within the first ninety days. But if the appointee holds office for a longer period than that, he can then only be removed by charges being preferred against him, and proved after a regular hearing.

The spirit of the service is generally good. Much new life has been enthused into it throughout the entire country in the past few years. Any medical officer who shows special aptitude for certain lines of work is given all possible encouragement. The State displays as a rule a fair liberality in providing books, scientific apparatus and instruments to the extent the work requires.

All that I have said in the foregoing concerning the service in New York State applies in a large measure to all the other States, with probably two chief exceptions—I refer first to the lack of civil-service examinations in most States, and to the influence of politics in making appointments. It is generally conceded that political influence is still felt in some of the western institutions. At the same time a very active campaign is going on now in the more progressive of these States in an effort to place the work of caring for the sick absolutely above and beyond the reach of political influence of any kind whatever. Salaries also, as a rule, are not as large in the institutions West and South as they are in the older institutions of the East. This is partly offset by the less expensive cost of living in those localities as compared with the East.

Special Positions.—In addition to the positions named in the foregoing there are several others which are usually very attractive to men who have had a particular training, and who desire to devote their life to some special scientific problem. These positions are generally in laboratories for the prosecution of pathological studies. A good many institutions have resident pathologists with well-equipped laboratories at their command. Special examinations are required for nearly all these, and the rate of compensation ranges from $1,500 to $5,000 a year. In some States that have a large number of hospitals, to a certain extent conducted along the same general lines, the laboratory work is combined in a central plant which is presided over by a director who is paid the larger sum.

In the mining districts of Pennsylvania and other localities, corporations employ physicians at regular monthly salaries. These salaries rarely exceed $30 to $40 a month, but the work is usually in an active community and the physician has a very good opportunity to do private work in the surrounding country.

Private Sanatoria and Health Resorts.—Especially in the Eastern States, but throughout the country generally, there are many private sanatoria that care for persons suffering from chronic diseases of one kind or another, and there are other sanatoria usually smaller that care for a more restricted class of invalids made up mostly of mild cases of nervous and mental diseases. The former institutions are often quite large, have a population of several hundred patients, and a staff of resident physicians numbering as high as ten to twelve or more; some of them usually being qualified for especial lines of work, such a surgery, pathology, etc.

Appointments in these institutions are made by the physician in charge, and as a rule without examination. The salaries paid range from $900 to $2,500 a year and maintenance. In the smaller sanatoria, that are especially numerous in the East and that care for nervous and mental cases, the salaries are considerably larger, ranging from $1,500 to as much as $5,000 a year, in addition to maintenance. Appointments in these smaller institutions are usually made by the physician who owns them or who directs the medical work in them, and rest solely upon personal choice.

Some of these private institutions are quite active in the up-to-date treatment of disease. Many are near large cities where members of the staff can have library and other special advantages.

I have not included in the foregoing a very large number of assistants in subordinate teaching positions in the various medical colleges of the larger cities. Many young physicians on leaving college take up work of this kind and are paid from $100 to $300 a year for it. In some lines of work the pay is better.

It is not the financial side of such teaching that is attractive, but the possibility of being in line for promotion and the public recognition of certain ability.

There is one word of caution to be said to young physicians, and it is this: If you go into institutional work with a purpose to stay in it only a year or so, maybe two or three years, be sure you leave it at the end of that time or before you have formed such routine habits of work that when you do give it up you will find yourself very unhappy in the new field of labor.

1110 North Charles Street.

SALARIED POSITIONS OPEN TO MEDICAL MEN IN THE LARGER CITIES.

By WILSON G. WOOD, M.D.,

NEW YORK.

The recent graduate in medicine has indeed a problem put before him. How to establish himself in legitimate practice? Though many a young man steps directly from his hospital service into a rapidly growing practice, and many another is so comfortably situated as to have little concern about the extent of his clientèle, the great majority are compelled to sit in disheartening idleness for months of the first few years, waiting for work. Not long ago a letter, published in one of the daily papers and purporting to be written by the friend of a physician, set forth the unenviable plight of one who without advantageous connections tries to gain a livelihood by entering into practice. After a bitter complaint, the writer went even so far as to inquire if the present precedents governing the practice of medicine were not utterly wrong. There

is indeed a very real difficulty in attracting a clientèle in any of the larger cities, but on the other hand it is coming to be recognized that active practice is only a part of the medical man's function, and nowhere is the opportunity for work requiring medical training but not restricted to the mere treating of disease greater than in the very centers where the establishment of the individual is most difficult.

No time could be more opportune for the consideration of this question than the present, since within a month or two another host of recent graduates will be looking for employment. While a majority of these no doubt think only of practising, a number will find more congenial employment in other ways, and even those who wish ultimately to practise medicine, will find convenient any work which renders them financial aid. It should be borne in mind by the seeker after positions which insure a fixed income, that, for the physician, most of the work outside of the practice of medicine can be only a temporary aid to a livelihood rather than an end in itself. With this in mind, we may consider some of the many ways in which a physician may supplement the income from his practice.

The Department of Health.—Of course the largest number of positions requiring medical knowledge is offered by the municipal health departments. Those offices of highest rank are of great importance in the community, and, while requiring considerable ability and special aptitude for administrative work, command a high degree of respect. They are usually filled by men who have had a large experience in public sanitation and are therefore attained only after work in lower positions. However, a great number of lesser opportunities are offered to men of no especial training.

A summary of these in the New York City Health Department will serve to indicate the character of the work in all such institutions. The first to be named are the commissioner of health (salary, $7,500) and the general medical officer ($5,000), who are officers of general administration and supervision. They are the chief advisers of the Board of Health. The general medical officer has supervision over the sanitary and contagious divisions of the department. A sanitary superintendent ($5,000) gives his attention to the execution of the technical details of the work in the same divisions, and he is directly responsible to the general medical officer. Five assistant sanitary superintendents ($3,500) have similar duties in the boroughs to which they are appointed. The two sanitary engineers ($2,400) who must possess much technical mechanical knowledge in addition to medical lore may be included in the list since the posts have been occupied by physicians. The two chief inspectors ($3,000 and $2,500) and the assistant chief inspector ($2,250) of contagious diseases, as the titles imply, investigate all reported cases of contagious disease through their aides, the diagnosticians and the medical inspectors. There are over twenty of the former and their salaries range from $1,200 to $1,800. After personal investigation they furnish the official diagnosis to the department in all cases of contagious disease, recommend if advisable the removal of patients to one or other of the contagious hospitals, and discharge them from the same after the termination of their illness. The four hundred or more medical inspectors have varied duties to which they are assigned by the inspectors of contagious diseases. These usually fall into one of three classes. (1) The vaccination of all persons in the district to which they are assigned; (2) the inspection of all pupils in the public schools for evidence of contagious disease, including affections of the eyes and skin; (3) routine inspection of cases of contagious and communicable disease reported from the district to which they are assigned. The inspector must visit the patient, see that the regulations of the department of health are obeyed during the patient's illness, and oversee the disinfection at the termination of the disease. In cases of diphtheria he will, if requested, administer antitoxin. During the summer the inspection is extended to the treatment of the children of the poor among whom the mortality from diarrhoeal diseases is so high. One of the medical inspectors is assigned to night work at the office of the department, several have duties in the hospitals and almost any other special work may be asked of them by the chief inspector. Medical sanitary inspectors ($750-$1,800), of whom there are between thirty and forty, investigate complaints from citizens regarding violations of the regulations of the department.

Superintendents of hospitals and hospital physicians ($1,200-$2,500) have duties similar to those of such officers in other like institutions. They are employed in the Willard Parker, Trachoma, Riverside, and Kingston Avenue hospitals. There are also two attending and twenty-one assistant attending physicians to these hospitals. They spend but little time in the work and receive only $300 or $600.

The vital statistics for the entire city are compiled by the registrar of records ($4,000) aided by his five assistants ($3,000). He also receives and grants death certificates, burial permits, etc.

Laboratory work in the department may be divided into clinical routine and research. The former done in the diagnosis laboratory is concerned with the results of Gruber-Widal tests, examinations of blood for malarial plasmodia and of sputum for tubercle bacilli. The latter consists in the manufacture of antitoxin and vaccine and such investigation as may seem desirable. The following are the titles and salaries of the positions in the laboratories: director of the research laboratory ($2,550), six assistants of the bacteriological laboratories ($1,800-$2,110), one assistant director of the vaccine laboratory ($1,800), one assistant director of the diagnosis laboratory ($1,800), twelve assistant bacteriologists ($1,200-$1,500), three bacterial diagnosticians ($1,000-$1,200), one medical instructor in the vaccine laboratory ($1,200), four pathologists ($1,200).

With the exception of the men employed in the diagnosis laboratory, these physicians must give all their time to the work, *i.e.* at least eight hours a day. The same is true of the sanitary superintendent, the chief and assistant chief inspectors of contagious diseases, the registrar and his assistants, hospital superintendents and resident physicians. The time required in the other positions varies greatly, but the average may be placed somewhere between three and eight hours a day. A new appointee can expect to fill only such positions as medical inspector, assistant bacteriologist, and hospital physician. Other posts are to be regarded as promotions from these.

While such work in the department of health may be of greatest financial assistance to the recent graduate, it rarely aids directly in the establishment

of practice, and if the latter is the ultimate aim of the individual he should relinquish his position in the department as soon as his circumstances permit.

The Department of Public Charities.—The following positions whose titles sufficiently indicate the required duties are open to medical men in the department of charities: one general superintendent of hospitals ($5,000), one medical superintendent ($1,800), one deputy medical superintendent ($1,200), two examiners in lunacy ($1,500), two examining physicians ($1,000 and $1,500), one visiting and two resident physicians. The examining physicians are occupied between four and seven hours a day. All the time of the other men with the exception of the visiting physician is required in the performance of their duties. The positions are filled by appointment from the civil service lists.

In the *Department of Correction* there are five salaried positions filled by physicians. Three visiting physicians to the city prisons ($1,200-$1,500) give only a part of their time to department work. They visit all employees who are absent from duty because of sickness. Two resident physicians who receive $1,200 and maintenance give all their time to hospital work and if away must furnish a substitute. All appointments are made from the lists of the civil service commission.

The Police Department.—Twenty-five surgeons are at present employed in this department and their positions are considered very desirable. The applicant must be a regularly licensed physician and surgeon of New York State, a citizen of the United States, and a resident of New York City. He is appointed by the police commissioner from the lists compiled after competitive civil service examination. Once appointed he can be dismissed only because of dereliction of duty. The salary is $3,500. The police surgeon is subject to call at any moment when not actually attending a member of the police force. In a word he practises medicine among the policemen. A good opportunity is afforded him to build up a lucrative business among his patients' families and friends, for he is allowed to treat both at his usual rates. The competition for these positions is very keen, and without powerful political influence it is doubtful if anyone can secure the appointment to one of the infrequent vacancies. The successful applicants are usually men of considerable experience in practice. Such work is of course distinctly worth while, since it is a direct aid to the establishment of a clientèle as well as generously paid employment.

The Fire Department.—In the fire department eleven physicians are employed. "They must be skillful physicians and surgeons" who have attained through examination a high rank on the lists of the civil service commission. They receive $3,300 per annum and rank as chiefs of battalion. Practically all of their time is required in the performance of their duties. One or more of the surgeons attends daily at fire headquarters for the examination of such members of the uniformed employees as may be directed to report to him for that purpose, and for the examination of candidates. They are charged with the examination of all members of the force who may report sick, and they attend all such who have contracted illness or have received injuries when on duty. They answer all alarms of fire over second alarms. These positions are not quite so desirable as are those in the police department, for the surgeon has less time to himself and is in a way simply an officer in the department.

In the *Department of Street Cleaning* three physicians are employed. They visit sick employees and report on their condition, but are not obliged to treat them. These are civil service positions and command a salary of $1,800. About half of the incumbent's time is taken up with this work.

Department of Education.—Two medical examiners are employed by the Department of Education to report on the physical condition of applicants for teachers' licenses. They receive $1,700 salary and are appointed on the nomination of the president of the Board of Education. A number of medical men are lecturers in the evening schools; but though medical training is a desirable qualification for this work it is not required by the appointing power. The same is true of the department of physical education.

The Health Department of the State of New York.—In New York City five physicians are in the employ of this department. The health officer of the port of New York ($12,500), who is appointed by the Governor of the State, spends all his time in the direction of the work of his assistants, of whom there are four, viz., two deputy health officers for the inspection of passengers and crews of incoming vessels to the port, salary $2,700 with a small yearly increase; one medical assistant detailed for hospital work at Swinburne Island Hospital, salary, $2,400; and one bacteriologist ($2,500). These four men are appointed by the health officer without civil service examination. All but the bacteriologist live at Quarantine, and give all of their time to the work.

Corporations and Business Houses.—Not all opportunities for salaried employment are offered by public institutions. Private capital employs a number of professional men in all the large cities. Thus the street railways of New York depend to large degree on their paid physicians both to treat individuals who are injured by the cars of the company and to examine such individuals in order to determine the character and extent of the injury sustained, so that in case of a suit for damages expert testimony may be presented by the corporation. The experts are necessarily men of considerable experience and reputation; but the physicians who are called upon in emergencies need not be. Appointments are obtained through personal influence, the pay is fair, and only a part of the physician's time is required.

Not to be forgotten are the opportunities offered by the managements of the large department stores, who have recently undertaken to furnish their hundreds of employees with medical attendance during business hours, in the person of a paid physician who is required to spend nearly the entire day at the store. The remuneration is comparatively small, not more than $1,200 yearly, and the work is of no great aid in building up a practice, so that such positions are not advantageous from the medical man's standpoint. Nor, it must be confessed, in such cases is the service likely to be so beneficial to the patient as the close attention of the family doctor, chiefly because the company's physician is overworked and underpaid.

A somewhat similar scheme has not long since been inaugurated by some of the large manufacturing concerns. These positions are more desirable, for much less time is required at the establishment

and the physician attends the employees at their homes, becoming acquainted with them and their families, and thus having an opportunity to extend his practice.

There are published in every great city several medical journals which depend almost entirely upon graduates in medicine for editorial work, reviews, abstracts, etc. Depending on the amount of time spent, the return from such work varies from a modest addition to one's income to a generous salary. The work, though, of course, not easily done by all, is pleasant to those who have an aptitude for it, and stimulates the worker to a close study and wide reading of the new medical knowledge.

Private laboratories offer positions to a few medical men, and the universities employ in their athletic departments one or two physicians. In both these cases medical knowledge *per se* is of rather minor importance, the chief requirement being special training. The universities also employ a visiting physician, who is paid a small salary besides what fees he can collect from the students whom he attends.

Not many medical men are born teachers. A comparatively few, even, have the opportunity to teach. But to those who have and who realize that there are a science and an art of teaching, the former to be diligently studied, the latter to be acquired only after much careful practice, the delight of teaching medicine will strongly appeal. In no other way can theoretical medicine be so well studied as by instructing others in its principles. Such men should accept the first opportunity that offers in the medical school, for not only will they themselves thereby gain much, but if they can really teach, they will supply a great and at present not entirely satisfied want.

It is hard to recommend to any physician that he try to obtain employment as a "lodge doctor." The members of the so-called benevolent or fraternal organizations expect to be treated whenever they are ill, offering as a recompense their yearly dues which rarely exceed two dollars per capita. Here again it is very doubtful if the patient receives such good care as he would at the hands of the family doctor. The liberty of practice of the physician is certainly seriously curtailed.

From the foregoing it is clear that in seeking employment other than that of actual practice the physician has two courses open to him. He may temporarily or permanently give up all thought of practising and devote himself as a paid employee must to the service of his employer, or he may choose some work which, though, as a rule, less well paid, admits of his applying a part of his time to his individual interests. Much work of the former character must be done, trained men are necessary to do it, and of these physicians are perhaps most easily available. On the other hand, to give up all one's time to the service of the municipality, a private corporation, or a "lodge" looks very much like surrendering the freedom which members of the medical profession have long enjoyed. It would seem wise for the individual graduate to choose in the beginning between the two fields of licensed practice and regularly paid employment. An alternative course which is to make the regular practice of medicine his chief work and to choose such extra occupations as will not only not interfere with but will directly aid in extending it is perhaps the wiser

LEGAL RIGHTS AND OBLIGATIONS OF THE MEDICAL PRACTITIONER.

By ARTHUR N. TAYLOR, LL.B.,

OF THE NEW YORK BAR.

THE physician, newly equipped with the medical knowledge and experience which in the light of the present is deemed adequate to enable him to enter upon the important work of caring for the health of his fellow-beings, and imbued with the importance of his trust, and the great diligence and care with which he must apply his skill and science, is apt to overlook the legal relations into which his work brings him with his patients and the State. This oversight is not so serious, however, as it might at first thought seem, for in the vast majority of cases the physician's professional and legal obligations run parallel, so that when he carefully and conscientiously gives his patients the best of his knowledge and skill, he is fulfilling the obligations imposed upon him by the law. It is desirable, however, that the physician should have at least a general knowledge of these legal obligations, and, in the course of his practice, it will be of much value to him to understand the rights which accrue to him through his professional intercourse with his patients. It is, therefore, the purpose of this article to encompass, so far as its limits will permit, the subject of the legal rights and obligations growing out of the relations existing between physician and patient.

The physician, because of the right granted to him by the State to practice medicine and surgery, is, in the absence of an express statute to that effect, under no obligation to exercise his professional skill upon whomsoever may apply for treatment, but may arbitrarily withhold his services, even though an adequate fee is tendered when the request for medical attendance is made. But the physician having accepted or agreed to attend a patient, it becomes his duty to continue the treatment and call as frequently and long as the nature of the case may require, and in determining when he may discontinue his visits he is required to use ordinary skill and care. This obligation may, however, be terminated by giving to the patient a reasonable notice that the services will not be continued, so as to enable the patient to procure the attendance of another physician. Should the physician discontinue his visits without first giving reasonable notice of his intention so to do, and at a time when by the exercise of reasonable care and skill he should know that further attendance was necessary, he would thereby become liable to the patient for all resulting damages.

The physician, or in fact any person acting as a physician, having undertaken to attend a patient professionally, the law immediately creates by implication a contract on his part that he is possessed of a "reasonable," "ordinary" or "proper" degree of skill and knowledge, that in the exercise of this skill and knowledge he will use reasonable and ordinary care and diligence, and in all cases of doubt he will use his best judgment.

These fundamental requisites are well recognized, but in their application nice questions frequently arise. There are certain well-recognized rules for determining what is proper skill and learning. Probably the first in order of these is that the physician's proficiency must be tested by the general principles of the school of medicine which he pro-

fesses to practice. The meaning and justice of this rule is too manifest to require elaboration or illustration. The benefit of this rule has, however, been denied to a clairvoyant by the Supreme Court of Wisconsin, which, in a well-considered opinion, held that clairvoyants do not constitute a school of medicine, that there can be no school of medicine unless there are recognized rules and principles of practice for the guidance of the members whereby different members of the same school would prescribe substantially the same remedy for the same condition; that clairvoyants had no such recognized rules and principles, but each practiced after his own method, the only feature of their method of practice recognized by them in common being the manner of ascertaining the patient's condition. On the other hand, the Supreme Court of New Hampshire, in a recent case, has recognized, in effect, that there is a "school" of Christian Science. An action was brought by the patient to recover for malpractice where a healer, in treating the patient for appendicitis had instructed her not to lie down but to keep about the room the same as usual and to eat anything she wanted. The court was of the opinion that there was nothing in this treatment to show that the healer had deviated from Christian Science methods and practice.

The second rule is that the physician's skill and knowledge must be judged in the light of the advanced state of medical science, so that it would not do for a surgeon of thirty-five years' standing to fail to operate in a suitable case of knee-joint disease because he was taught in college never to open the knee-joint, antiseptic surgery being then unknown; nor could a physician justify the administration of general anesthetics in case of an operation on the eye, the use of general anesthetics in the particular case being dangerous, by showing that authorities twenty-five years ago laid down the inflexible rule that an operation on the eye should never be undertaken without complete anesthesia. And third, the skill and knowledge required of the physician shall be those ordinarily possessed by physicians practising in similar localities; thus the limitations or opportunities of environment are taken into consideration, and so a different standard would be imposed in case of a country physician with little or no opportunity to practice surgery being suddenly called upon to perform a difficult and complicated surgical operation, from that by which the skill of a physician practising in a large city and frequently taking part in such operations would be judged. This rule, it will be observed, is that the standard required is the skill ordinarily possessed by physicians practising *in similar* localities, not in his particular locality, otherwise it might be urged that when all in a given locality are ignorant quacks one could not be held wanting in skill because he possessed as much skill and knowledge as any of the others.

The physician bringing the requisite knowledge and skill to the treatment of a case, the next obligation imposed by the law is that he will use reasonable and ordinary care and diligence in its application, and the question of what is reasonable care and diligence must always be answered in the light of the circumstances and conditions of the particular case. Thus it frequently happens that the physician is called to attend a patient when the most casual examination is sufficient to inform him beyond question of the patient's condition and to enable him to prescribe with a moral certainty as to results, while on the other hand it not infrequently happens that a patient's condition is such as to require the most searching and continued examination to discover the malady or combination of maladies from which he is suffering, and after the physician has satisfied himself as to the diagnosis, the method of treatment may require equal thought and care. It is manifest that care which would have been adequate in the former case, would in the latter case be negligence, for which the physician would be liable for injury directly resulting.

The physician is not, however, necessarily required to use care and skill proportionate to the severity of the injury or disease treated, as such requirement would fall little short of guaranteeing results.

The requirement that the physician use proper and ordinary care in the exercise of his protessional intercourse with his patients applies equally in determining when he may safely discontinue his visits, to which reference has been heretofore made. It is also the physician's duty to use proper care upon discharging his patients to instruct them or their nurses as to the treatment or conduct to be observed during convalescence. A failure to exercise such care, resulting in injury to the patient, may render the physician liable in damages to the extent of such injury. And so must the physician use due care, in going from patients affected with contagious or infectious diseases to other patients, not to communicate such diseases; and, again, the question of what is due care in one to be answered in the light of the attendant circumstances—the character of the disease which is subject to communication, the susceptibility or condition of the patient to whom the physician goes after attending upon such case of contagion or infection—these are things which must be taken into consideration in determining what degree of care and precaution is requisite; in short, what degree of care and precaution would be exercised by an ordinarily careful and competent physician under the same or similar circumstances; such care is that which the law requires.

The physician also impliedly contracts with his patients that in all cases of doubt he will use his best judgment. This requirement is one which inures to the benefit of both the physician and patient. The physician is confronted by a complicated and serious case, perhaps one in which the recognized remedies cannot be used because of conflicting tendencies, or because of the peculiar condition of the patient, or perhaps because of an idiosyncrasy. At such time, when the physician cannot act by precedent, but must do the thing, and perhaps without time for reflection, which his judgment tells him is best under the circumstances, it can but be of great comfort to him to know that if he uses his best judgment he is doing all that the law requires, and this knowledge will in turn leave the physician's mind as free as possible from worry and dread lest the results be deleterious, and so secure to the patient the very best services the physician is capable of rendering.

The physician must not, however, presume too much upon the "exercise of his best judgment," for its exercise is always based upon the possession of professional knowledge and skill without which there can be no "best judgment." In a case in which the diagnosis would leave no question in the mind of a capable and competent physician as to the patient's condition, and in which the method of treatment for that condition is well recognized and generally accepted by the profession, a depart-

ure from the established practice would be at the physician's peril.

The foregoing obligations of the physician are unaltered by the fact that his patient may be a charity patient, or that he may intend to make no charge; the only thing necessary to bring all these implied obligations into full force and effect is that the relation of physician and patient exists.

It will be seen that the physician does not impliedly contract that he will cure or even benefit his patients, but merely that he has reasonable and proper skill and knowledge, that he will exercise ordinary and proper care in the treatment of his patients, and that in all cases of doubt he will use his best judgment. These are the fundamental professional requisites prescribed by the law, and the physician who possesses and exercises them in all cases calling for their exercise will probably escape legal accountability for failure to obtain favorable results from the treatment of his patients.

Possessing and exercising all of these qualities, a physician may, however, through inadvertence or indiscretion, transgress the law, or may, without an actual infraction, come so near to the line as to be subjected to the annoyance and burden of defending a suit. Thus the question has frequently arisen whether the physician was authorized to perform a certain operation, the testimony of the patient being that he was to operate only if a specified condition were found and then the extent of such operation to be limited, while the defendant's testimony is that he consented to operate only with full discretion in the matter. In such cases it is a question of fact to be determined by the jury whether the physician has exceeded his authority and is liable. The question of whether a physician was authorized to operate upon a wife has several times been the subject of litigation, the husband testifying that the operation was contrary to his express instructions, but the evidence showing that the operation was understood and approved by the wife. In such cases it has been held that the instructions of the husband were immaterial, the wife having full authority to assent to and authorize an operation upon herself in the face of her husband's protests. And so a physician has been subjected to suit when he was called by one of his regular patients to examine a domestic for the purpose of ascertaining whether the domestic was pregnant, the domestic at first objecting to the examination, but finally submitting, though unwillingly.

The performance of an autopsy without consent from the party having authority to consent, has also been the subject of suits prosecuted successfully against physicians. The law is very strict in prohibiting such operations except when the decedent's condition was such as to render an autopsy necessary to determine the cause of death; and even in such cases the cautious practitioner will either procure consent to open the body, or, if practicable, turn the case over to the coroner. The parties from whom such a consent is properly obtainable are: First, the husband or wife of deceased; second, if no husband or wife survives, then the children; third, if there is no husband or wife and no child, then, first the father, second the mother; fourth, after them the brothers and sisters of the deceased; fifth, after them the next of kin according to the common law, to the remotest degree, according to the law of distribution of personal property.

A peculiar case of liability arose some years ago in which a physician took a young unmarried man to a house where he was called to attend a confinement case, the circumstances being such that it would have been difficult if not impossible for the physician to have reached the house of the patient without the help and company of the young man. There being but one room in the house, the young man remained in that room with the patient and was present when she was delivered, the patient and her husband believing, as they testified, that the young man was a medical student. For this act the court severely censured the physician and affirmed a substantial verdict rendered by the jury.

The civil liability is not the only penalty which may flow from acts of mere inadvertence and indiscretion; such acts are frequently the foundation upon which criminal prosecutions and sometimes convictions are based. The space allotted to this article will not, however, permit the consideration of this phase of the physician's liability.

The physician having been called to attend a patient, and having responded, it becomes pertinent to inquire what rights inure to him by virtue of such professional relations and how he may, in case of necessity, enforce them.

Upon responding to a call to attend a patient the physician thereby becomes entitled to the regular fees for making a call, even though the patient may have so far recovered from his illness as to render the visit unnecessary or even though another doctor may have been subsequently called and rendered the desired services, there being no question of negligence or delay precluding the right to such fee. He also becomes entitled to a like fee for each subsequent visit which, by reason of the character of the case, he deems it necessary to make.

The amount of fee to which a physician becomes entitled by reason of such attendance is a matter governed by custom and practice, the custom of the particular locality governing. If the customary price for a visit is one dollar, then a physician who, in response to a request for services, calls upon a patient with no understanding as the amount to be paid or received, becomes entitled to one dollar. If any physician should be dissatisfied with such rate he could, of course, by express understanding or agreement with his patients, fix a rate to suit his ideas.

The rate of fees for performing operations is also subject, to a certain extent, to the custom of the locality, though the character of this class of work is such that the price cannot be thus regulated to such a degree as the fees for ordinary medical attendance. An exception to the rule that local rates for fees, in the absence of express agreements fixing other rates or amounts, binds the physician, is found in cases in which physicians or surgeons from a distance are called because of their peculiar fitness to attend or operate upon a patient. In such case the fee chargeable is properly based upon the rate usually charged by such physician or surgeon.

In case of consultation, the patient without express agreement becomes liable to pay the consultant's fee; and this rule is so firmly established that an agreement between the patient and the attending physician that the attending physician will pay such fee will not release the patient from paying the consultant unless the consultant is informed of such arrangement.

The physician having earned a fee and having had his request for payment refused, it becomes necessary to determine whether to resort to suit to enforce the payment. To determine this question

it is necessary to consider the several steps of making proof and the several questions which may be raised.

First, is the physician a legally qualified practitioner? In all States where the question has been passed upon except the State of Missouri, it is held that one not a legally qualified practitioner may not sue; therefore a negative answer to this question, except as to one practising in Missouri, is equivalent to the determination that there is no cause of action, and such disability to recover applies not only as to professional services, but as well to claims for medicines furnished to the patient.

The foregoing question having been answered in the affirmative, it then becomes necessary to determine whether the claim is barred by the statute of limitations. As these statutes differ more or less in the several States, this question can be answered only by recurring to the statute of the particular State in which the cause of action accrued.

The next step is the matter of proof of the physician's license. This is a technical matter which may best be left entirely to the counsel.

The next step is the proof of employment; if the physician is employed by the party to whom the services are rendered or by a party who is under obligations to provide medical services for the patient, then proof of such employment is not necessary. Under such circumstances proof that the services were rendered and accepted will be sufficient; but if the employment is by some third person who is not primarily liable for the services rendered, this step in the case is very important and the character and sufficiency of the proof are matters to be submitted to counsel.

The next step in proving the claim is to show the services rendered; this is a step which is frequently if not usually fraught with difficulty.

Laws have been enacted in many States to the effect that a physician shall not be permitted to testify to information which he shall have acquired in attending a patient in a professional capacity and which shall have been necessary to enable him to act in that capacity. Among these States are: Arizona, Arkansas, California, Colorado, Idaho, Indiana, Iowa, Kansas, Michigan, Minnesota, Mississippi, Missouri, Montana, Nebraska, Nevada, New York, North Carolina, North Dakota, Ohio, Oklahoma, Oregon, Pennsylvania, South Dakota, Utah, Washington, West Virginia, Wisconsin, and Wyoming. This inhibition, it is held, is not waived by a plea of general denial on the part of the defendant, the effect of which is to render it necessary for the physician to prove all of the facts upon which he is to recover. This places the plaintiff in a trying situation, where he cannot testify with any degree of detail regarding the services rendered, and yet he must prove the rendering of the services or fail in his suit. Under such circumstances he will, to use the words of Mr. Justice Hait of the Court of Appeals of New York, be permitted to "testify to his employment, the number of visits made, to the examinations, prescriptions and operations, and if the defendant objects to his describing them, he may testify as to their value.

In giving testimony in proof of the services rendered it will be difficult, if not impossible, when considerable time has elapsed since the rendering of such services, for the physician to testify with sufficient certainty and accuracy as to the items of service, without having recourse to his books of account. At such times, if he made or saw the entries made in his books of account when the facts were fresh in his mind, and remembers that it then stated the facts correctly, he may refer to the books to refresh his memory. Subject to certain limitations, the books in most of the States are themselves admissible as evidence of the facts stated in them. This is, however, a matter which is subject to limitations and rules differing more or less in the several States; for instance, in New York the books of account of a physician will be admitted as evidence, there being no objection to them upon the ground that they disclose privileged communications, upon his showing them to have been his regular books of account, that he kept no clerk who was familiar with his business and competent to testify regarding the facts stated in the books, that some of the work or services charged was persome of the work or services charged was performed, and that he kept correct accounts. In many of the States it is necessary that the books shall be books of original entry. The question of admissibility of evidence in support of the physician's claim is a technical one upon which counsel must pass, therefore it is not thought advisable to go into the question in great detail. A few words may, however, well be devoted to the manner of keeping books of account. It may upon the trial be necessary to state more or less particularly the nature of each service rendered, therefore the book of original entry should be so kept that by referring to it years after the services charged were rendered, the physician may be able to testify particularly as to each item, and if permitted, describe the character of the services rendered. It must be remembered, however, that in most States information gained while attending the patient professionally is not permitted to be disclosed in court, therefore in such jurisdictions a book of accounts, which plainly and explicitly states the character of ailment for which the patient is treated, will manifestly be inadmissible. It has been suggested by the writer of this article* that this difficulty may be overcome if the physician will adopt a code of arbitrary signs and characters whereby he may be able to describe the ailments of his patients and the character of the services rendered to them in such a way that this portion of the information contained in the book will be wholly unintelligible to all others than himself, and therefore not subject to the objection that it discloses confidential communications. If the accounts be kept in this way, each item being charged separately under the date upon which the service was rendered with a specific sum charged after such item, then the book will be admissible to show dates and amounts, and may also be used on trial by the physician for the purpose of refreshing his memory, and enabling him to testify in detail so far as the law of the particular State will permit.

The foregoing anticipates that the party against whom the suit is brought is still living. Should he be dead and a suit against his estate become necessary, the situation becomes further complicated by the fact that the physician will not be permitted to testify as to any transaction with deceased relative to the subject matter of suit. In such a case, there will be nothing for him to do but submit his books and corroborate them by the testimony of some one else, and indeed, whether the books will be admitted in such a case is not clear, there being conflicting decisions upon the question. When the books are held admissible, and are not so kept as to show the nature and date of each service rendered

*"The Law in Its Relations to Physicians," p. 204. Edition of 1903, p. 211.

and amount payable therefor, or when such information is partly recorded in characters unintelligible to others than the physician, then they are subject to the objection that they are too indifinite to prove the account, and are of no value except when supported by strong corroborating evidence. If, on the other hand, the books contained all of these necessary facts in characters intelligible to the court, they would, in States recognizing professional communications as privileged, be wholly excluded upon objection by the opposing party. In cases of this sort the person most frequently capable of corroborating the physician's books and testimony is his wife; but is her evidence competent? At common law the wife was not permitted to testify for or against her husband in a suit to which he was a party. This rule is now altered by statute in most States but still remains the law in a few. In those States in which the wife is competent as a witness under ordinary circumstances, the courts are divided upon the question whether she will be permitted to testify when the other party to the suit is dead or insane, the courts of Maryland, Mississippi, Nebraska, New Hampshire, New York and South Dakota holding that she will; the courts of Illinois, Indiana, Iowa, Maine, Pennsylvania and West Virginia holding that she will not be permitted to testify.

Fortunately it is infrequent that suit must be resorted to for the collection of claims from the estates of decedents, but to collect a claim from such estate it is usually necessary to comply with the practice and forms of the particular jurisdiction in which the estate is being administered.

The limits of this article will permit of but a brief outline of the method of presenting a claim for payment and a hasty examination of the considerations to be entertained in determining whether to resort to suit.

Ordinarily the first step in the administration of an estate is the application for letters of administration, or, where there is a will, the application for probate and for letters testamentary. Upon the issuance of letters of administration or letters testamentary it is proper for the claimant to present his claim to the administrator or executor, as the case may be. Shortly after issuance of letters to the administrator or executor he may, and usually does, under direction of the court, advertise for the presentation of claims against the estate, fixing a date within which all claims shall be filed. In some jurisdictions all claims which are not filed within the time limit are forever barred, while in other jurisdictions such claims merely forfeit the right to share in the first distribution of assets, but may follow any remaining assets.

The manner of preparing the claim for presentation should next be considered. The required form is not the same in all States, yet if the physician will prepare his claim after the following directions it is believed that he will have complied with the strictest requirements of any State. The claim should be reduced to writing and should describe the general nature and amount and value of the services with as much particularity as possible. If a note or other instrument has been given, then a copy of it should be attached. Claims for services should be verified on oath, the oath containing substantially the following:—that claimant is a physician and surgeon, and has been duly licensed under the laws of the particular State to practice medicine and surgery; that the annexed account was for professional services rendered to decedent or to some one for whose medical attendance he may have been responsible, as the case may be; that the amount owing for such services is ——— dollars; that the claim is justly due and owing to ——— from the estate of said deceased; that no payments have been made thereon, and that there are no offsets against the same to the knowledge of this deponent.

The claim having been presented it will then be acted upon by the executor or administrator, who will allow it in whole or in part, as he is convinced of its validity and justness, or will reject it as a whole. If rejected, it is in most States, provided by statute that the claim will be barred in a short period of time, ranging from three months to one year, within which time claimant may commence suit on the claim.

Among the questions to be considered in determining upon the advisability of suing such a claim are: First, whether the claim is a valid claim against the estate. This is a question involving the consideration of the many defences which may be raised by a living defendant, and a few others which peculiarly appertain to claims against estates of decedents. For instance, the physician's bill for services rendered a deceased wife should be paid by the husband and cannot be enforced against the wife's estate unless it be shown that the husband has no property with which to pay the claim; or when services were rendered without intention of charging therefor, the physician expecting that he would receive a legacy sufficient to compensate him for all such services, the failure to receive such legacy will not enable him to maintain a claim against the estate. If, however, when such services are rendered there is a mutual understanding that the physician is to be compensated by legacy, then the failure to make such bequest will enable the claimant to maintain a claim for such services. Also in case of services rendered to members of one's family, there is a presumption that they were gratuitous, but this presumption may be overcome by proof that the services were rendered under an understanding that they were to be paid for, or under such circumstances as to show that when they were rendered the parties contemplated a pecuniary compensation therefor. This presumption becomes weaker as the relationship of the parties becomes more distant.

Second, whether the claim is susceptible of proof. The law relating to this question has been heretofore examined.

Third, the solvency of the estate. At common law claims presented against an estate and allowed were payable in the following order: (1) The necessary funeral expenses. (2) The necessary expenses of administration. (3) Debts of record due the crown. (4) Debts of record due the subjects, which include judgments, decrees, statutes and recognizances. (5) Debts by specialty founded upon a valuable consideration, that is those debts arising out of contract under seal. (6) Simple contract debts based upon valuable consideration. (7) Voluntary bonds or covenants. (8) Other voluntary debts. According to this scheme it will be observed that the physician's bill would belong to the sixth class unless he had secured a bond in liquidation of the account, in which case it would be advanced to the fifth class, or unless he had reduced it to judgment, when it would become a claim of the fourth class.

This order has, however, been altered in every

State, the most common order now existing being the following: (1) Funeral expenses. (2) Expenses of administration. (3) Expenses of last illness. (4) Judgments (abolished in a number of States). (5) Public debts (this in many States has a prior rank in the scheme). (6) Simple contract liabilities.

If an estate is solvent it will, of course, pay all of the claims of all of the classes, but in case it is insolvent, then it will pay the classes in their order to the full extent of the available assets, the class last reached receiving whatever there may be left and all of the creditors of that class getting a *pro rata* share of such amount. Therefore in determining the question of solvency, so far as the particular claim is concerned, it is necessary to determine, first, the class to which it belongs, and, second, whether there are assets enough to pay all of the claims of that and the preceding classes.

It will be observed that the scheme adopted by most of the States recognizes a class not recognized by the common law scheme, that is, the "Expenses of the last illness." The question of what constitutes the expenses of the last illness is often a very nice one and one which has given rise to many bitter contests. The general tendency of the courts is, however, to recognize all services rendered to the patient in attendance upon him for the disease of which he died as "expenses of the last illness," even though such attendance may have extended through a long period of time. In some cases, courts and juries have gone so far as to hold that services rendered through the year preceding death were "expenses of the last illness."

All of these questions being answered in the affirmative, the physician is then justified in determining to enforce his claim by suit, but as the consideration of some of these questions requires the exercise of judgment, fortified by an understanding of the technicalities of the law, the conclusion should be reached only after a conference by the physician with his counsel, in which all of the facts and circumstances are fully and frankly laid before the counsel.

50 Broadway.

POST-GRADUATE STUDY IN EUROPE.

By GEORGE MANNHEIMER, M.D.,

NEW YORK.

Several serious problems confront the American physician who wants to take up post-graduate work. Shall he go abroad or remain at home? What are the advantages of post-graduate instruction abroad? what are the requisites? how can he inform himself on these points?

There is no question as to the advisability of taking up post-graduate work in the great medical centers of Europe, if the physician can afford the time and expense and is familiar with the language of the country in which he intends to study. Let me emphasize this last point. There is a current opinion that a knowledge of the language is not necessary in Germany and Austria, as medical courses are given in Berlin and Vienna in English. There are a few such English courses, but they are insufficient to give either a special or an all around general training. If the physician intends to take up dermatology, for example, it will not suffice to see the patients demonstrated by some assistant who speaks English. He will naturally want to attend the clinics and lectures of the professor or head of the department, which are always given in the native tongue. On rounds he hears only German spoken. And how can he handle patients without speaking and understanding their language? My advice to the physician who wants to take up post-graduate work in Germany or Austria is, learn German before you start, not a smattering, but get a fair knowledge, then supplement this by such instruction as can be obtained abroad. In all university towns where many English-speaking students are found there are language teachers who are familiar with the specific needs of American medical students. Avoid boarding-houses frequented by Americans.

There are many advantages in post-graduate instruction in Germany and Austria to the recent graduate who wants to further pursue his studies as well as to the older practitioner who wants to brush up, to the one who wants to specialize, as well as to the one who wants an all around training.

1. The recent graduate who has failed to secure a hospital appointment at home can obtain an interneship or rather externeship at a university clinic. He does here the ordinary work performed by the house staff in American hospitals and he comes in close contact with the patients, professor, and assistants. Americans are preferred for this work as they are faithful and reliable and devote their whole time to their duties. This preference has brought about in some quarters a mild jealousy of German students toward their American confrères. The graduate who desires such a position needs only an introduction to the professor and an expression of his willingness to do the work. Neither diploma nor examination is required.

2. Older practitioners sometimes obtain the rights and privileges of internes, making the rounds with the professor and examining cases. This requires a suitable introduction to the professor and is available for only a short time.

3. The clinics and hospital divisions are under one head, generally a medical man of known merit, who has absolute control over his department. This is of great advantage to the practical working of the institution.

4. The directors or chiefs are not only teachers but they are original investigators who devote their time to the clinic and stimulate research work in their staff. These men are always ready to aid a student who is working on a problem or will give him a problem if he is looking for one. The materials of museums, libraries, and laboratories are at his disposal.

5. Patients lend themselves better to demonstration, examination, and experiment.

6. Post-mortems are obligatory, every part of the body being examined.

7. Some specialties originated abroad and special methods of diagnosis, treatment, and technique were created and are in use. Americans naturally want to go to the source of such specialties.

8. The teaching facilities are excellent. Mention may be made of the use of the epidiascope, with which almost every large clinic is equipped. By means of this projection apparatus not only temperature and pulse curves, illustrations, tracings, photographs, tables, etc., are thrown upon the screen, but entire organs and parts of the body. Microscopic slides under high or lower powers and with various methods of staining are made to pass in review, and if the class be small, the students sitting in front

of the screen are supplied with long poles by means of which they point to parts which they wish explained.

I would make special mention of the general use of the *x*-ray for teaching and diagnostic purposes. This branch is much further advanced in Germany than in the United States. Remarkable results have been achieved in the diagnosis of internal diseases. There are many experts and original investigators in this field who impress upon the physician the great value of the *x*-ray in the recognition of the finer details of internal lesions which cannot otherwise be discovered.

9. Research work is general and the facilities for carrying it out are so plentiful that any one who wishes to take it up seriously is welcomed. Directors of laboratories appreciate work done in their institutions since it redounds to their credit as well as to the investigator.

There are several methods of arranging for post graduate instruction. There are courses given under the auspices of the University during the regular term and during vacation time, the latter designed mainly for physicians. There are also regular courses given by the members of the association of private docents. These courses are for a definite period, generally one month at a fixed fee. Besides these, special courses can be arranged by an individual or by a group of physicians, covering any desired period of time and any subject. Fee by agreement.

There are, moreover, many sources of instruction which are virtually free to physicians. These are the meetings of the local medical societies where something original and interesting is always presented and where the visitor has an opportunity to take the measure of eminent men with whom he could not otherwise come in contact. In all large German cities the municipality arranges medical courses for its physicians, charging them a nominal registration fee. These courses are held by the chiefs of the local hospitals and institutes who present there the best material available. Demonstrations are sometimes held in the form of colloquia in which the professor gives the history and status of a case and then calls for opinions and discussion.

No one is barred from regular university clinics and lectures.

Visiting physicians should not neglect to inspect the therapeutic departments attached to public medical institutions. There they can learn what can be accomplished by physical therapeutics, a branch of the healing art little known and sadly neglected by the average American practitioner. I refer here to hydro,- mechano,- kinesio,- photo- and electro-therapy. All these appliances are also found in private sanatoria, numbers of which are conducted successfully all over the Continent. Visiting physicians are always welcome. One should not fail to visit a tuberculosis sanatorium and day camp near the medical center at which he is staying. Psychotherapy, which American physicians leave to quacks and unprofessional healers, can be studied abroad under recognized specialists.

A few words about the modes of living and general conduct abroad. The "Baedecker" is by far the best guide book published. The visitor should conform to local conditions and customs and he should not constantly refer to the superiority of American ways and manners. Bragging and brusqueness are the main failings of Americans abroad and should be avoided. The Germans are enthusiastic in their work and communicative, qualities which should be appreciated.

Visitors either rent a furnished room with or without breakfast or stop at a boarding house, called "pension" in Europe. See that light, heat, and service are included in the price. Baths are extra. All large towns have excellent public bathing establishments. The cost of living varies with the town, the location, and the demands of the individual, a fair average being from $25 to $50 a month.

Most American physicians who go abroad for post graduate instruction go to Vienna and Berlin. Both cities have medical societies composed of Americans who hold weekly scientific meetings and maintain headquarters where newcomers can obtain information on all subjects connected with their stay and studies. Such information can be obtained by correspondence.

The American Medical Association of Vienna is so well organized that it almost monopolizes the best courses, and no time is lost in traveling about, as almost every scientific demand can be met within the confines of the general hospital. These two points and the attractiveness of life in Vienna make it still the most popular medical center of Europe for the American. This does not imply that one can learn more in Vienna than in Berlin; in fact, some subjects are better represented in the latter city. If a man has a good introduction to a professor in one of the smaller university towns, and intends to take up the professor's specialty, he should by all means go to him, because he is in close touch with the head, unhampered by scores of visitors. It is a mistake to suppose that the small universities have a small supply of material. They all draw from a large outlying district. A special advantage of these small towns is the low cost of living.

I wish to draw attention to the mass of medical material available for study in such cities as Hamburg, Frankfort, Cologne, and Nuremberg, not university towns, but with splendidly equipped hospitals and laboratories.

A knowledge of French is absolutely necessary if one intends to take up post graduate work in Paris. Without a fair knowledge of the language it is simply a waste of time and money to go to that country for instruction.

In Paris, there are no regular post graduate courses and the physician must either make private arrangements with a professor or else take chances with the undergraduates at the medical school. Paris is preeminent in three branches, dermatology, genito-urinary work, and original research. Two courses in bacteriology are given annually at the Pasteur Institute. A physician who wants to visit the hospitals and clinics can obtain a card from the Bureau of Public Assistance, admitting him to these institutions as often as he wishes. As there is no system of post graduate instruction the newcomer must do his own hustling to get in touch with the work he intends to undertake. There is a Continental Anglo-American Society in Paris and an American Art Students' Association whose members can give their countrymen more good advice about living in the French capital than can be found in volumes on the subject.

During the past decade, London has taken a prominent place for post graduate work, and has attracted many American physicians through its post graduate association, officially known as The

Associated Schools of Medicine of London for Post Graduate Teaching. By an arrangement between 15 of the largest general and special hospitals of the city, joint cards of admission are issued for the clinical instruction given in these hospitals. These cards are only issued to physicians and admit them to the wards and out-patients' rooms, attendance at operations and post mortem examinations, clinical lectures and post graduate courses. The fees are 7 guineas, or about $36 for three months, 10 guineas ($51) for six months and 5 guineas for each additional month. The advantages of this system of post graduate instruction are, an enormous amount of clinical material, the opportunity of seeing the work and hearing the opinions of a large number of eminent physicians in every branch of medicine, the privilege of taking many courses in divers branches.

If the physician intends to specialize, such general ticket is useless except for his specialty, and in that case he would do better to arrange for a special course or join a regular course at one special hospital. There are several post graduate hospitals and schools not connected with the Post Graduate's Association where such special courses can be taken. These are conducted like the post graduate schools in the United States. It would be invidious to make comparisons between them as each has certain points of superiority and the teaching capacity is a matter of personal opinion.

Owing to the distances between many of the hospitals in London, much time is lost in going from one to the other. If the visitor has but a short time at his disposal, he should take a room near the one in which he expects to do the most work and arrange for breakfast, not for full board. Many of the principal hospitals are in poor sections of the city, and the visitor may be obliged to choose between poor quarters with a saving of time and lessened expense, or good quarters with loss of time and more expense.

Several of the smaller cities give post graduate instruction in their hospitals and medical schools, but there is no advantage in any except in the School of Tropical Medicine in Liverpool.

A final word. Don't fail to make copious notes of what you see and hear, and enlarge upon them. Let the numerous new ideas and impressions stimulate you to new work.

Résumé.—A knowledge of French in France and German in Germany and Austria is indispensable. Courses are given in English in Berlin and Vienna, but are insufficient. In Berlin and Vienna the student selects his teacher, pays him and their relations are personal. In London, the student pays the school and there are no personal relations between student and instructor. In Paris the physician is either the guest of the professor or an ordinary visitor.

In Berlin and Vienna, docents give regular courses on one subject generally lasting one month. The instruction is individual or to a small group. In London, the courses are given to classes, a general ticket being good for three months or more, and covering all subjects taught in a number of hospitals and schools.

Americans have exceptional opportunities to obtain interneships in German and Austrian clinics.

Paris is best for dermatology, genitourinary work, and bacteriology.

Berlin is best for original research, pathology, diseases of the stomach, and metabolism.

Vienna is best for general clinical instruction and most specialties.

London is good for all-round work, but is not preeminent in any.

Liverpool leads in tropical medicine.

STATE MEDICAL PRACTICE LAWS.

By R. J. E. SCOTT, M.A., B.C.L., M.D.,

NEW YORK.

GYNECOLOGIST TO THE DEMILT DISPENSARY, AND TO THE WEST SIDE GERMAN DISPENSARY.

The medical student, after four years of hard work, and passing his examination, receives his diploma and becomes a Doctor of Medicine. It is somewhat humiliating to him to find that this diploma and title give him absolutely no right to practise medicine. He has now to satisfy the requirements of the Board of Examiners of the State in which he desires to locate. These State boards are very necessary, and serve a threefold function: (1) To protect the public from quacks; (2) To conserve the interests of the practitioners already settled in the State; (3) To keep out incompetent practitioners.

The requirements of these State boards may be classified under four heads: (1) General and Preliminary, dealing with age, moral character, residence, and possibly citizenship in the United States; (2) Preliminary or Academic Education; (3) Medical Education; and (4) The Medical Examination that has to be passed.

The requirements under (1) generally give no trouble. (2) *General Education.* The demands under this heading differ very materially in the various States; some requiring either an academic degree, or at any rate a full four-years' course in a high school or substantial equivalent; while other States are content with legible handwriting and fair spelling; and still a few remain in which no preliminary education is asked for. (3) *Medical Education:* The requirements here are nearly as varied as those for the preliminary education. Most of the States now require a full four-years' course in a first-class medical school; some States still require only three years; one or two States seem content with even less; and it would be hard to say with how little real medical education a license can be obtained, if only due care is observed in the selection of the State in which to practise. (4) *The Examination:* Every State has its own idea of what

is right and proper here. In most of them a good, fair examination is put up; and a properly qualified student will have no difficulty in passing it. In a very few States the fairness of the examinations has been questioned; and certainly, at times, questions have been set which showed the incompetency (not to use a harsher term) of their author. The number of papers may vary anywhere from half a dozen to a score, but it is not to be inferred that the examination in the State with twenty papers is more difficult than that in the State with only six. Some State boards manage to compress all the main subjects of a medical education within the compass of from seven to ten papers; while others delight to spread themselves out, and set a separate paper on every specialty, as if they were making a bid for universal specialists.

If at any time the practitioner wishes to move from one State to another, he may again have to satisfy the medical examiners of the State he desires to enter. Though at first sight this seems an intolerable hardship, it will, on a careful investigation of the facts mentioned above and a perusal of the various requirements given below, appear no more than right. Naturally, the States whose requirements are the most slender, are eager to "exchange" or "reciprocate" with those that require more. Reciprocity implies equality, more or less; and this cannot be said to obtain between two States, one of which demands four years in a high school and four years in a first-class medical school, while the other asks for no education at all, either preliminary or medical, and where an applicant need never have entered a school of any sort or description. Reciprocity *may* come by and by, but the problem is a large and complex one, and this is not the occasion on which to discuss it.

In spite of the fact that these examinations are supposed to ascertain the applicant's fitness *to practise medicine and surgery*, it is curious to note that in some States there is no examination on Practice, Materia Medica, Therapeutics, and even Surgery. The reader must not be beguiled into believing that such omission makes the examination any easier; or he may learn to his cost that a State which does not require surgery sets a separate paper on histology, or embryology, and demands a much greater knowledge of bacteriology than the general practitioner either acquires or uses.

The object of this paper is to place before practitioners a *résumé* of what the different States require. The information given will be on the four topics stated above, with further mention of any reciprocity that may exist between the different States. All points bearing on the laws governing the constitution of the Board of Examiners, whether the members are appointed by the governor of the State or by the medical societies, prosecution for illegal practice, penalties, etc., will be omitted, as not of general interest.

As a general rule, the student who has taken an academic course for four years in a high school and then spent four years of medical study in a recognized medical college, will have no difficulty in gaining admission in any State. Those who have not this standard of qualification will see what States they had better avoid.

The information given is, as far as possible, up to date, but, in every case, would-be applicants should apply to the secretary for the latest requirements; this is particularly necessary with regard to reciprocity requirements, which are apt to vary from time to time. At the same time applicants should try to obtain samples of the questions that have been used on former occasions. These questions will show the scope of the examination better than anything else. For the past two and a half years the MEDICAL RECORD has published questions and answers of the leading States.

Passing examinations is a kind of gymnastics that belongs to youth, and to youth only; therefore these examinations should be taken at the earliest possible date. The day a man leaves college he has, probably, more of that kind of "knowledge" which delights examiners and is of little use to anyone else, than he is ever likely to be possessed of again.

A word about preparation for these examinations may be in order. The recent graduate has modern books, and in all probability he will experience no difficulty in reviewing the various subjects required of him. If he has neglected some subjects (say anatomy and chemistry) for a couple of years, he will certainly have to go over them carefully. So, too, if the State board that he has to face is one that peddles out all the specialties over quite a series of papers, he will need some reliable guide to steer him past that portion of the track.

The practitioner who has exchanged vast quantities of theoretical knowledge carefully acquired at college, for the more useful but (to examining boards) less satisfactory practical knowledge, will need all the help he can get; and to one or both of these classes, the following list of books will probably be of service. In compiling this list, we are mindful of the fact that many men have as good and perhaps even better books with which they are already familiar; such men would be unwise to exchange the tried and trusted for the new. But those who are rusty, or who have but little time, will find here books which the writer has proved, from a ten-years' experience in preparing men for these examinations, to be admirably adapted for the purpose. In every case the smallest book compatible with safety has been mentioned. It is well to remember that many books, very serviceable to the practitioner, are almost useless for examination purposes. For the benefit of students and practitioners preparing for these examinations, the present writer has compiled a series of volumes of questions and answers covering nearly all the subjects required; this is referred to as the State Board Examination Series, and the subjects contained therein are denoted in the following list by an asterisk:

*Anatomy.	Part V of Morris' Anatomy (Surgical and Topographical Anatomy) and either Nancrede's or Potter's Compend.
*Physiology.	Ashby's Notes, or Collins and Rockwell.
*Chemistry.	Witthaus' Essentials.
*Surgery.	Cunning's Aids, or Stewart's Manual.
*Obstetrics.	King.
*(*a*) Gynecology.	Penrose.
*Pathology.	Green, or Thayer.
*(*b*) Bacteriology.	Archinard.
*Hygiene.	Egbert
Medical Jurisprudence.	Dwight's Epitome, or Reese.
*(*c*) Toxicology.	Witthaus' Essentials.
*Practice	Hughes, or Stevens.
*(*d*) Eye.	May.
*(*d*) Ear.	Buck's First Principles.
*(*d*) Nose, Throat, and Ear.	J. J. Kyle's Compend or Manual.
Children.	McCaw's Aids.
*(*b*) Skin.	See Practice.
*Diagnosis.	Greene; and the Books on Surgery, Practice, and Children.

*Materia Medica and *Therapeutics.	Hare, or Potter.
*(e) Histology.	Radasch's Compend.
*(f) Nervous.	See Practice
*(f) Mental.	Hughes' Practice.
*(c) Physics.	Brockway.
General.	The State Board Examination Series, referred to above, and Gould and Pyle's Pocket Cyclopedia.

*State Board Examination Series.
(a) In volumes on Surgery and Obstetrics.
(b) In volumes on Surgery and Pathology.
(c) In volumes on Chemistry.
(d) In volumes on Surgery, Pathology and Practice.
(e) In volumes on Anatomy and Physiology.
(f) In volume on Pathology and Practice.

Résumé of the Requirements in the Different States.

Alabama.—All persons proposing to practise medicine in this State must undergo examination, irrespective of any diploma they may hold or of certificate obtained elsewhere. A diploma is not required as a prerequisite for examination. The examination is on the following subjects: Anatomy; Chemistry; Physiology; the Etiology, Pathology, and Symptomatology of Diseases; Surgery; Obstetrics and Obstetrical Operations; Gynecology; Physical Diagnosis; Hygiene and Medical Jurisprudence; Diseases of the Eye, Ear, Nose, and Throat.

The fee for examination is $10. An unsuccessful applicant will be entitled to a second examination within one year without the payment of an additional fee.

Examinations are held at Montgomery, in January and June.

There is no reciprocity.

Chairman of the State Board of Medical Examiners is Dr. W. H. Sanders, Montgomery, Ala.

Alaska.—By the *proposed law* all applicants must produce satisfactory testimonials of good moral character and a diploma from a legally chartered medical college, the requirements of which shall have been in no particular less than those of the Association of American Medical Colleges at the time such diploma was granted.

Applicant must further pass an examination of ten questions each in Anatomy, Physiology, Chemistry, Toxicology, Bacteriology, Pathology, Surgery, Obstetrics, Materia Medica, Therapeutics, and Theory and Practice of Medicine. In case he should fail in the first examination he may be reexamined after not less than six months.

Examinations are held at Juneau, on the first Tuesday of May and October.

Fee for registration and recording, $35.

Reciprocity may be allowed on requirements equal to those of Alaska. Fee $25.

Arizona.—Every applicant must be over twenty-one years of age, of good moral character, and a *bona-fide* resident of Arizona. No person shall receive a license to practise medicine within the territory unless he or she shall have: *First:* Obtained a diploma to practise medicine, regularly issued by a lawfully organized medical college, and, *Second:* Obtained a certificate entitling him or her to practise medicine, as prescribed in the Revised Statutes of Arizona, 1901, or shall have passed a satisfactory examination prescribed by the provisions of an act to regulate the practice of medicine in the Territory of Arizona, approved March 18, 1897; or, *Third:* Practised medicine within the Territory of Arizona continuously for five successive years preceding the date fixed for the taking effect of this act; or, *Fourth:* Upon examination by the Board of Medical Examiners of Arizona, shall show to the satisfaction of the board that he or she possesses sufficient knowledge and skill to practise medicine. All recent graduates will have to pass the examination.

Examinations consist of ten questions each in Anatomy, Physiology, Chemistry, Materia Medica, and Therapeutics, Obstetrics, Gynecology, Practice, Pathology, Surgery.

The applicant must obtain a total average of 75 per cent., provided that in no branch shall the percentage be less than 60, except in Practice, Obstetrics, Gynecology, and Surgery, in which branches the minimum is placed at 80 per cent. The fee for examination is $10 and for license $2.

Examinations are held at Phœnix, on the first Monday of January, April, July, and October.

Reciprocity, none.

Secretary of the Board of Medical Examiners, Dr. Ancil Martin, Phœnix, Ariz.

Arkansas.*—Applicants must be of the age of twenty-one years and must pass an examination in the following subjects: Anatomy, Physiology, Chemistry, Materia Medica, Surgery, Theory and Practice of Medicine, and Obstetrics. The questions are elementary and practical. If, in the opinion of the board, the applicant possesses the necessary qualifications, a certificate will be issued to him. The fee for examination and registration is $10.

Examinations are held four times a year, on the second Tuesday in January, April, July, and October; and at such places as a majority may agree upon.

Reciprocity, none.

Secretary of Board of Examiners, Dr. F. T. Murphy, Brinkley, Ark.

California.—Each applicant must furnish satisfactory testimonials of good moral character; and also two autographed (unmounted, cabinet size) photographs taken within sixty days of the date of application. Each application must be accompanied by a statement signed by the principal of the high school or college attended, showing the subjects studied and the time devoted to each subject (how many hours a week and for how many weeks).

The Medical Law and Rules of this Board require of an applicant who desires to practice medicine or surgery to file a diploma issued to him by a legally chartered Medical College, the requirements of which were at the time of graduation in no particular less than those prescribed by the Association of American Medical Colleges of that year.

In addition to the above, every applicant must be personally examined on the following subjects: Anatomy, Physiology, Bacteriology, Pathology, Chemistry and Toxicology, Hygiene, Obstetrics, Histology, Gynecology, General Diagnosis. There will not be less than ten (10) questions on each subject. The examination must be in whole or in part in writing, and in the English language. A general average of 75 per cent. and a minimum of 60 per cent. on each subject must be attained. A credit of five points is allowed for each ten years of legal practice.

The fee for examination is $25.

Reciprocity, none.

Examinations will be held on the first Tuesday of April and August in San Francisco, and on the first Tuesday of December in Los Angeles.

Secretary of the Board of Medical Examiners,

*Legislation is now pending, and may change these requirements.

Dr. C. L. Tisdale, 929 Butler Building, San Francisco, Cal.

Colorado.—Applicants must present evidence of good moral character, and a photograph. The following may be granted licenses *without examination:*

A. All applicants who graduated prior to July 1, 1893, must furnish satisfactory evidence of having been matriculated in, and graduated from, legally chartered and reputable medical colleges (at that time in good standing with the Colorado State Board of Medical Examiners), which required a preliminary examination for admission and a minimum of two winter courses of instruction.

B. All applicants who graduated between July 1, 1893, and July 1, 1895, must furnish satisfactory evidence of having ben matriculated in, and graduated from, legally chartered and reputable medical colleges (at that time in good standing with the Colorado State Board of Medical Examiners), which gave a minimum of twenty weeks of instruction in each twelve months of three separate years, and which required of their graduates of 1894 and 1895, as a matriculation regulation, a diploma of graduation from some approved university or literary, scientific, normal or high school, or a preliminary examination in all the several subjects embodied in the curriculum of graduation examination from a high school.

C. All applicants graduating between July 1, 1895, and January 1, 1900, must furnish satisfactory evidence of having been matriculated in, and graduated from, legally chartered and reputable medical colleges (at that time in good standing with the Colorado State Board of Medical Examiners), which required of their graduates of 1896, 1897, 1898, and 1899 as a matriculation regulation a diploma of graduation from some approved university, or literary, scientific, normal or high school, or a preliminary examination in all the several subjects embodied in the curriculum of an approved high school, and which gave to its students graduating in the years above named four full courses, in four separate years.

All such applicants under A, B, and C, must have received a license to practice medicine in at least one of the United States of America, in which State the standard of licensure is, in the opinion of the Colorado State Board of Medical Examiners, equal to that of the State of Colorado, and must have been continuously and actively engaged in the lawful practice of medicine since receiving said license.

D. All applicants graduating after January 1, 1900, must furnish satisfactory evidence of having been matriculated in, and graduated from, legally chartered and reputable medical colleges, which enforce the following requirements:

(1) As evidence of preliminary education, as a minimum requirement any of the following: (a) A diploma or certificate of graduation from an accredited four-year high school; (b) a certificate signed by a principal of a regularly organized approved high school, the faculty of a recognized literary or scientific college or university, State Superintendent of Public Instruction, County Superintendent of Schools, or some person or board duly appointed by the State Board of Medical Examiners to conduct such an examination; of having successfully passed an examination in all the several branches embraced in the curriculum of a four years' high school course.

(2) A full course of instruction of four terms in four separate years of nine months each.

All such applicants must have received a license by examination to practice medicine in at least one of the United States of America, in which State the standard of licensure is, in the opinion of the Colorado State Board of Medical Examiners, equal to that of the State of Colorado, and must have been continuously and actively engaged in the lawful practice of medicine since receiving said license, and must have been so engaged in the practice of medicine at least one yeaer.

The subjects of written, oral or clinical examinations shall be as follows: Anatomy, Physiology, Chemistry, Symptomatology, Toxicology, Pathology, Surgery and Obstetrics (exclusive of Materia Medica and Therapeutics). The credentials of applicants relating to their general reputation, their preliminary education and courses of study they have pursued; the degrees they have received; the number of years they have been engaged in the lawful practice of medicine; their experience in general hospitals, medical departments of the army, navy and public health and marine hospital service; licenses granted to them by other States and countries; and their experience as teachers of medicine, shall be given due consideration by the Board in conducting its examinations. Upon investigation of an applicant's credentials the Board shall, when convinced that an applicant is qualified to practise medicine, grant a license thereon without further exaxmination.

The fee for license is $25. Two-fifths of the fee will be returned if the license is not granted.

Regular quarterly Board meetings and examinations are held in Denver on the first Tuesday in January, April, July and October. Examinations cover a period of four (4) days. (First day, oral and clinical; second, third and fourth days, written examination.)

Secretary of State Board of Medical Examiners, Dr. S. D. Van Meter, 1723 Tremont Street, Denver, Col.

Connecticut.—All candidates must be graduates of some reputable medical college and must present their diplomas (or a certificate from the dean of the medical college) for inspection to the secretary of the board at the opening of the session. As evidence of preliminary education, a diploma from a high or preparatory school (or equivalent) must also be presented. All candidates must undergo the regular examination conducted in writing, and consisting of ten questions each in Anatomy; Surgery; Materia Medica, including Therapeutics; Practice, including Pathology and Diagnosis; Obstetrics, including Gynecology; Physiology; Medical Chemistry and Hygiene. In order to be admitted to practice the applicant must obtain a general average of 75 per cent. In no branch shall his percentage be less than 60, and in Practice, Obstetrics, and Surgery, the minimum requirement will be 65 per cent.

The examination fee is $15.

Examinations are held on the second Tuesday of March, July, and November, at the City Hall, New Haven, Conn.

Reciprocity, none.

Secretary of the Medical Examining Board, Dr. Chas. A. Tuttle, New Haven, Conn.

Delaware.—"Applicants must furnish satisfactory proof of good moral character, be more than twenty-one years of age, have obtained a diploma from some reputable literary or scientific college,

or a certificate from the faculty of Delaware College, signed by the president and attested by the secretary thereof, that he or she is qualified to enter the freshman class of the Latin scientific course of the said college; and have received a diploma conferring the degree of Doctor of Medicine, from some legally incorporated medical college, which, in the opinion of the Medical Council, was in good standing at the time of the issuing of the said diploma. Applicants who have received their degree in medicine after the passage of this act, must have pursued the study of medicine for at least four years, including four regular courses of lectures of not less than seven months each, in different years, prior to the granting of said degree, in some legally incorporated medical college or colleges, approved by the Medical Council.

The examinations are written, and comprise the following subjects: Anatomy, Physiology, Hygiene, Chemistry, Surgery, Obstetrics, Practice of Medicine, Pathology, Diagnosis, Therapeutics and Materia Medica. An average of 75 per cent. is required in order to pass the examination. The fee for the examination is $10. In case of failure, another examination can be taken after not less than six months and not more than two years without payment of additional fee.

Reciprocity is permissible with other States having requirements practically the same as those of Delaware. Fee, $50.

Examinations are held at Dover twice a year on the third Tuesday in June, and the second Tuesday in December.

Secretary of the Examining Board, Dr. J. H. Wilson, Dover, Del.

District of Columbia.—Only those who hold the degree of doctor of medicine are admitted to examination. Those who have received such degree before June 30, 1898, must have studied medicine not less than three years, and those who have received it after that date must have studied not less than four years, before graduation. The examination is both written and oral. It includes Anatomy, Physiology, Chemistry, Bacteriology, Pathology, Materia Medica and Therapeutics, Hygiene, Histology, Practice of Medicine, Surgery, Obstetrics and Gynecology, Diseases of the Eye and Ear, Medical Jurisprudence, and such other branches as may be from time to time determined by the Board of Medical Supervisors.

The fee for examination is $10.

Examinations are held quarterly on the second Tuesday in January, April, July and October.

Reciprocity. Licenses may be issued without examination upon the basis of licenses issued by other States and Territories under conditions equivalent to those of the District of Columbia, provided that said State or Territory grants similar privileges to licentiates of the District of Columbia.

Secretary of the Board of Medical Supervisors, Dr. George C. Ober, Washington, D. C.

Florida.—It shall be the duty of the board of examiners to examine thoroughly every applicant for certificate or qualification to practise medicine in any of its branches or departments, upon the production of his medical diploma from a recognized college upon the following-named subjects: Anatomy, Physiology, Surgery, Gynecology, Therapeutics, Obstetrics and Chemistry.

The examination fee is $15.

Examinations are held twice a year, generally in April or May, and October or November.

Reciprocity. None.

Secretary of the State Board of Medical Examiners, Dr. J. D. Fernandez, Jacksonville, Fla.

Georgia.—All applicants must be graduates of an incorporated medical college, requiring not less than three full courses of study of six months each. Applicants must pass a satisfactory examination on Anatomy, Physiology, Chemistry, Surgery, Obstetrics, Gynecology, Practice, Materia Medica and Therapeutics, Diagnosis. An average of 75 per cent. is required. The fee for the examinations is $10; but a candidate who has failed in his examination can take any subsequent examination without paying an additional fee.

Examinations are held twice a year, the first about the time of graduation from the medical colleges of the State, the other on the second Tuesday in October.

Reciprocity is allowed by law with States having an equal standard and requirement with the Georgia Board, provided these other States accord similar privileges to the licentiates of the Georgia State Board. Fee, $10.

Secretary of the State Board of Medical Examiners, Dr. E. R. Anthony, Griffin, Ga.

Idaho.—Applicants must be of good moral character, citizens of the United States, or have declared intention of becoming such, and must be graduates of a recognized reputable medical college in good standing and must present their diploma to the board for inspection. Every applicant must be examined. The examinations are wholly in writing, and embrace the following twelve branches or subjects, with ten questions on each subject, viz.: Anatomy, Physiology, Chemistry and Toxicology, Materia Medica and Therapeutics, Diagnosis, Theory and Practice, Hygiene, Obstetrics, Gynecology, Surgery, Pathology, and Histology. A general average of 75 per cent. is required by law to entitle applicant to receive a license. The fee for examination is $25; in case of failure one re-examination after six months and before one year is allowed without payment of additional fee.

Examinations are held on the first Tuesday in April and October.

Reciprocity, none.

Secretary State Board of Medical Examiners, Dr. W. F. Howard, Pocatello, Idaho.

Illinois.—Application for license to practise must be made in writing, accompanied by the examination fee and with proof that the applicant is of good moral character, and that he is a graduate of a medical college or institution recognized by the Board. He will be required to present to the secretary of the Board, at the examination, an unmounted photograph of himself, taken recently, which is filed with the application.

The applicant must also present documentary evidence of preliminary education—the minimum to be a diploma or certificate of graduation from a high school; a certificate signed by the principal of a regularly organized high school, or by the examiner of the faculty of a recognized literary or scientific college or university, or by the State superintendent of public instruction, or a superintendent of public schools, of having successfully passed an examination in all the several branches embraced in the curriculum of a four years' high school course.

Examinations are conducted in writing in the following subjects: Anatomy, including Histology and Embryology, 10 questions; Chemistry, 5 questions; Etiology and Hygiene, 5 questions; Physi-

ology, 7 questions; Neurology, 3 questions; Materia Medica and Therapeutics, 10 questions; Pathology and Bacteriology, 10 questions; Surgery, 10 questions; Physical Diagnosis, 5 questions; Ophthalmology and Otology, 3 questions; Pediatrics, 2 questions; Obstetrics, 10 questions; Gynecology, 6 questions; Laryngology and Rhinology, 2 questions; Medical Jurisprudence, 2 questions; Practice, 10 questions. An average of at least 75 per cent. is required for a passing grade.

The Board will accept as an equivalent of part of the examination required satisfactory evidence of five or more years of reputable practice, and will allow a credit of 1 per cent. on the required average of 75 per cent. for each year of such practice on the part of a candidate for certificate up to a maximum allowance of 30 per cent.

The fee for the examination is $10. If the applicant is successful a further fee of $5 is charged for certificate of license to practise.

Examinations are held in Chicago quarterly.

Reciprocity exists under certain conditions with Iowa, Kansas, Maine, Maryland, Michigan, Nebraska, New Jersey, North Dakota (after July 1, 1905 only), Ohio, South Carolina, Tennessee, Utah, Vermont, West Virginia, Wisconsin and Wyoming. The license must have been obtained after examination.

Secretary State Board of Health, Dr. J. A. Egan, Springfield, Ill.

Indiana.—Every applicant must be a *bona-fide* resident of the State six months before he can receive a license to practise.

An examination is required of all candidates. The subjects for examination are Anatomy, including Histology and Embryology; General Surgery, Materia Medica and Therapeutics, Medicine, Obstetrics, Pathology and Bacteriology, Chemistry, Etiology and Hygiene, Physiology, Neurology, Gynecology, Laryngology, Rhinology, Medical Jurisprudence, Physical Diagnosis, Ophthalmology and Otology, and Pediatrics.

The examination consists of 100 questions, making a total of possible points 1,000; 750 points are required to pass.

The examination fee is $25.

Examinations are held in Indianapolis on the fourth Tuesday in May and October.

Only graduates of reputable medical colleges are admitted to the examinations. Application for examination, accompanied by diploma, preliminary credentials required for entrance into medical college and fee, $25, should be on file in this office at least five days prior to the date for examination. Every applicant is required to send to the secretary of the Board, at least ten days before the date of examination, a recent, *unmounted* photograph of himself.

Reciprocity exists, under certain conditions, with the following States: District of Columbia, Georgia, Iowa, Kansas, Kentucky, Maine, Maryland, Michigan, Minnesota, Missouri, Nebraska, Nevada, New Hampshire, Ohio, Tennessee, Texas, Utah, Vermont, Virginia, West Virginia, Wisconsin and Wyoming.

The Secretary of the Board of Medical Registration and Examination is Dr. W. T. Gott, Crawfordsville, Ind.

Iowa.—Every applicant must present a certificate of good moral character, and evidence of preliminary education as follows: (1) A diploma or certificate of graduation from a fully accredited four-year high school or college; or (2) evidence of having passed the matriculation examination of a recognized literary or scientific college; or (3) a certificate of successful examination equivalent to the matriculation examination by the faculty of any reputable university or college, or by the State Superintendent of Public Instruction; or (4) the applicant must pass an equivalent examination before one of the special examiners, approved by this Board or by the State Board of Medical Examiners.

All persons beginning the practice of medicine in the State of Iowa must submit to a written examination in the following subjects: Anatomy, Chemistry, Materia Medica, Obstetrics and Gynecology, Pathology and Histology, Physiology, Practice and Surgery. And in addition thereto shall present diplomas from medical colleges recognized as in good standing by the Iowa State Board of Medical Examiners; and all persons receiving their diplomas subsequent to January 1, 1899, shall present evidence of having attended four full courses of study of not less than twenty-six weeks each, no two of which shall have been given in any one year.

The Board requires a general average of 75 per cent.

The examination fee is $10; in case of failure, a re-examination may be taken without payment of additional fee.

Reciprocity exists under certain conditions with: Colorado, Georgia, Illinois, Indiana, Kansas, Kentucky, Maine, Maryland, Michigan, Minnesota, Missouri, Nebraska, Nevada, New Hampshire, New Jersey, North Carolina, Ohio, South Carolina, Texas, Utah, Virginia, West Virginia, Wisconsin and Wyoming. Fee, $50.

Secretary of the State Board of Medical Examiners, Dr. Louis A. Thomas, Des Moines, Iowa.

Kansas.—All persons intending to practise medicine and surgery shall apply to the Board at any regular meeting, or at any other time or place as may be designated by the Board, for a license. Application shall be made in writing, and shall be accompanied by the fee of $15, together with the age and residence of the applicant, proof that he or she is of good moral character, and satisfactory evidence that he or she has devoted not less than three periods of six months each, no two within the same twelve months, or, if after April 1, 1902, four periods of not less than six months each, no two in the same twelve months, to the study of medicine and surgery. All such candidates shall submit to an examination of a character to test their qualifications as practitioners of medicine or surgery, and which shall embrace all those topics and subjects a knowledge of which is generally required by reputable medical colleges of the United States for the degree of doctor of medicine; provided, that graduates of legally chartered medical institutions of the United States or foreign countries in good standing, as determined by the Board, may be, at the discretion of the Board, granted a license without examination.

Examinations are held at Topeka on the second Tuesday in February, June and October.

Reciprocity: The Board may in its discretion accept, in lieu of examination or diploma, the certificate of the Board of Registration and Examination of any other State or Territory of the United States or any foreign country whose standards of qualification for practice are equivalent to those of this State.

Secretary of the State Board of Medical Regis-

tration and Examination, Dr. R. A. Light, Chanute, Kan.

Kentucky.—An examination is required of all applicants. Only *bona fide* residents of this State and graduates of recognized colleges located within the United States will be admitted to the examination. The application must be accompanied by an unmounted photograph of the applicant, on the reverse side of which must be his or her full signature, duly attested, under the seal of some official of this State authorized to administer oaths.

The subjects for examination are Anatomy, including Histology and Embryology; Physiology, Pathology, Chemistry, Surgery, Obstetrics, Gynecology, Bacteriology, Hygiene, Opthalmology, Otology, Medical Jurisprudence, Mental and Nervous Diseases, Etiology and Physical Diagnosis. The law requires a general average of 70, and a grade of not less than 60 in any branch.

Examinations are held at least twice a year at places and dates decided on by the Board.

Fee for examination is $10.

Reciprocity: The Board reciprocates with the following States, under certain conditions: District of Columbia, Georgia, Indiana, Iowa, Kansas, Maine, Maryland, Michigan, Nebraska, New Jersey, New Mexico, North Dakota, Ohio, South Carolina, Tennessee, Vermont and Wisconsin.

Secretary of the State Board of Health, Dr. J. N. McCormack, Bowling Green, Ky.

Louisiana.—Applicants must be twenty-one years of age, of good moral character, and possess at least a fair primary education. Applicants must also present to the Board of Medical Examiners a diploma from a medical college in good standing, such standing to be determined by the Board. An examination must be passed in Anatomy, Physiology, Chemistry, Obstetrics, Gynecology, Pathology, Physical Diagnosis, Surgery, Therapeutics and Hygiene. Seventy-five per cent. must be obtained. The fee for the examination is $11. Examinations are held twice a year in New Orleans.

Temporary licenses are granted under certain conditions.

Reciprocity: The Louisiana State Board of Medical Examiners recognizes at present certificates of examination issued by the following State Boards: Colorado, Connecticut, Delaware, District of Columbia, Illinois, Indiana, Iowa, Kansas, Kentucky, Maine, Maryland, Michigan, Minnesota, Missouri, Nebraska, Nevada, New Hampshire, New Jersey, New Mexico, New York, North Dakota, Ohio, South Carolina, Texas, Utah, Vermont, Virginia and Wisconsin. Fee, $25.

Secretary of the State Board of Medical Examiners, Dr. F. A. Larue, 211 Camp street, New Orleans, La.

Maine.—Each applicant must give satisfactory proof of being twenty-one years of age, having good moral character and of being a graduate of some reputable medical school or college, having power to confer degrees in medicine, and in good standing, and maintaining a standard of preliminary education and of medical instruction approved by the Board. He shall also supply the secretary with a recent unmounted photograph of himself or herself, duly certified to before a notary public.

The standard of medical instruction which the Board will approve is three years of medical study and three courses of lectures for those who graduated previous to 1902, and four years' study and four courses of lectures after that date. Five years of reputable practice before 1901 will be accepted in lieu of one year's study. The Board, in its classification of diplomas, will recognize only those medical colleges that require as a condition of admission the equivalent, at least, of a high school education, in addition to the full four years' attendance in a medical college. This applies to those students matriculating in 1908 and after. Colleges or medical schools complying with these rules will be approved by the Board as far as preliminary education and medical instruction is concerned.

It is further necessary to pass an examination in: Anatomy, Physiology, Pathology and Histology, Practice of Medicine, Materia Medica, Surgery, Obstetrics and Gynecology, Chemistry and Toxicology, Disease of Eye, Ear, Nose and Throat, Hygiene and Medical Jurisprudence.

A general average of 75 per cent. shall be necessary to license, provided, however, that in no branch shall the percentage be less than 60 per cent.

The fee for examination is $10, and in case of failure a second examination may be taken within one year without further fee. The fee for certificate is $2, and is returned if the applicant fails.

The Board will hold meetings in March, July and November at such places and on such dates as they may select.

Reciprocity now exists with: Colorado, Delaware, District of Columbia, Georgia, Illinois, Indiana, Iowa, Kansas, Kentucky, Louisiana, Maryland, Michigan, Minnesota, Missouri, Nebraska, Nevada, New Jersey, North Dakota, Ohio, Oklahoma, South Carolina, Tennessee, Texas, Utah, Vermont, Virginia, West Virginia, Wisconsin, and Wyoming.

Secretary of the Board of Registration, Dr. William J. Maybury, Saco, Me.

Maryland.—Applicants must be twenty-one years of age, of good moral character, must submit evidence of a competent common school education, and must have received a diploma from a medical school in the United States requiring a four years' course, and recognized by the American Medical College Association or the Intercollegiate Committee of the American Institute of Homœopathy. Medical students, at the end of their second year of study, who have, as verified by the certificate of the dean of the college which they have attended, completed the studies of Anatomy, Physiology, Medical Chemistry, and Materia Medica in said college, may be examined in these subjects. All applicants must pass an examination in Anatomy, Physiology, Medical Chemistry, Surgery, Practice of Medicine, Materia Medica, Therapeutics, Obstetrics, and Pathology. Fee, for the examination, is $15. In case of failure the fee is not returnable, but the applicant is allowed a re-examination without further fee.

Examinations are held in Baltimore on the first Tuesday in June and the second Tuesday in December.

Reciprocity: The Board is authorized to recognize certificates issued by other States whose requirements are of as high a standard as those of Maryland, provided such other State will, in a similar manner, recognize the certificates issued by the Board of Maryland. Reciprocity exists at present with District of Columbia, Georgia, Illinois, Indiana, Iowa, Kansas, Kentucky, Maine, Michigan, Minnesota, Missouri, Nebraska, New Hampshire, Ohio, Oklahoma, South Carolina, Texas, Vermont, Virginia, West Virginia and Wisconsin, subject to requirements and fees imposed by the respective States.

Secretary of the Board of Medical Examiners, Dr. J. McP. Scott, Hagerstown, Md.

Massachusetts.—Applicants must furnish proof of being twenty-one years of age or over, and of good moral character; there are no legal requirements as to either general or medical education. A medical diploma is not necessary, and non-graduates in medicine are admitted to the examination. Examination is compulsory for all applicants. According to *the law*, "Examinations shall be wholly or in part in writing in the English language, and shall be of a scientific and practical character. They shall include the subjects of Anatomy, Surgery, Physiology, Pathology, Obstetrics, Gynecology, Practice of Medicine and Hygiene, and shall be sufficiently thorough to test the applicant's fitness to practise medicine." But, according to *the Board of Registration*, "the subjects on which the examinations are principally conducted are Anatomy and Histology, Physiology and Hygiene, Pathology and Bacteriology, Surgery, Obstetrics and Gynecology, Diagnosis and Therapeutics, and Pediatrics and Toxicology."

Intending candidates will be interested in the following extract from the last annual report: "In the examinations held this year (1908) the Board has made a beginning in conducting them along the lines of practical work in microscopy, in the laboratory and in demonstrations on the manikin. Our experience is that such work is practicable in several of the subjects examined on. A mixed examination, written, oral and practical, is, we believe, best calculated to insure an actual test of one's qualifications to enter upon the practice of medicine."

When general averages fall below 75 per cent., examinations are regarded unsatisfactory. A person refused registration by reason of failure to pass a satisfactory examination is entitled to two reëxaminations within one year, without filing a new application or paying an additional fee. The fee for the examination is $20.

Examinations begin on the second Tuesday of March, July, and November. Special examinations may also be held at the same time in May and September.

There is no reciprocity.

Secretary of Board of Registration, Dr. Edwin B. Harvey, State House, Boston, Mass.

Michigan.—Applicants must furnish proof of being over twenty-one years of age, and of good moral character. Each applicant must also have received, previous to the beginning of his course in medicine, a diploma from a recognized and reputable high school, academy, college, or university, having a classical course, or shall pass an examination equivalent at least to the minimum standard of preliminary education adopted by the board. Each applicant must also have received a medical diploma from a reputable and approved college of medicine within the United States, having at least four years' course of eight months each calendar year, as shall be approved and designated by the Board of Registration in Medicine.

Applicants must satisfactorily pass an examination on Anatomy, Physiology, Chemistry and Toxicology, Histology and Embryology, Bacteriology, Pathology, Surgery, Practice of Medicine, including Mental and Nervous Diseases, Diseases of Children, and Diseases of the Eye, Ear, Nose, and Throat, Obstetrics, Gynecology, Medical Jurisprudence, Hygiene and Public Health, Materia Medica and Therapeutics, and such additional subjects made necessary by advances in medical education as the board may designate. An average of at least 75 per cent. is required. The fee for examination is $25.

Examinations are held at Ann Arbor on the second Tuesday of June, and at Lansing on the second Tuesday of October.

Reciprocity exists under certain conditions with District of Columbia, Indiana, Iowa, Kansas, Kentucky, Maine, Maryland, Minnesota, Missouri, Nebraska, Nevada, New Hampshire, New Jersey, New York, North Dakota, Georgia, Ohio, South Carolina, Texas, Utah, Vermont, Virginia, West Virginia, Wisconsin, and Wyoming. Fee $50.

Secretary of the State Board of Registration, Dr. B. D. Harison, 205 Whitney Building, Detroit, Mich.

Minnesota.—Each applicant is required to make an affidavit setting forth his age, place of residence, preliminary education, time and place of each course of medical lectures, and date of graduation. The affidavit must be corroborated by the exhibition of his diploma or a certificate from the Dean of the Medical College showing that he has completed the prescribed number of courses and is a candidate for graduation. Graduates of medical colleges granting advanced standing for work done at other than medical colleges shall not be eligible to the examinations given by this Board.

Each applicant, if he graduated or completed his final course of lectures after January 1, 1899, must show proof that he has attended four full courses of lectures at a recognized medical college, no two courses being in the same year. Each applicant, if he graduated after July 1, 1887, and prior to January 1, 1899, or completed his final course of lectures during that period, must show proof that he has attended three full courses of lectures at a recognized medical college, no two courses being in the same year. Applicants who graduated at a recognized medical college prior to July 1, 1887, must show proof of having attended two courses of lectures at a medical college. An examination is required of each and every one on: Anatomy, Physiology, Chemistry, Histology, Materia Medica, Therapeutics, Preventive Medicine, Practice of Medicine, Surgery, Obstetrics, Diseases of Women and Children, Diseases of the Nervous System, Diseases of the Eye and Ear, Medical Jurisprudence, and such other branches as the board shall deem advisable. Ten questions are given on each paper. A general average of 75 per cent. must be attained. "Handwriting of candidates must be legible, and orthography must not be such as will disgrace the medical profession." Fee for the examination is $10. This fee is not returned in case of failure.

Examinations are held at St. Paul, on the first Tuesday of January, April, June, and October.

Reciprocity is allowed under certain conditions with: District of Columbia, Indiana, Iowa, Kansas, Maine, Maryland, Michigan, Missouri, Nebraska, Nevada, New Hampshire, New Jersey, Ohio, South Carolina, Tennessee, Utah, Wisconsin, and Wyoming. Fee, $50.

Secretary of the State Board of Medical Examiners, Dr. W. S. Fullerton, St. Paul, Minn.

Mississippi.—"The application for license must state: (1) The applicant's name in full; (2) his place of residence and post-office address; (3) his nativity and age; (4) the time spent by him in

medical studies: (5) the name and post-office address of the preceptor under whom medical studies were pursued; (6) courses of medical lectures attended; (7) name of medical school attended; (8) if a graduate of a medical college, name thereof; (9) time spent in hospital; (10) time spent in the practice of medicine, if any; (11) school or system of practice chosen, and (12) references as to his personal character." Everyone must be examined. Examinations are in Anatomy, Chemistry, Obstetrics, Materia Medica, Physiology, Pathology, Surgery, and Hygiene. The fee for the examination is $10.25.

Examinations are held at Jackson, twice a year, on the second Tuesday in May and October.

Reciprocity, none.

Secretary of the State Board of Health, Dr. S. H. McLean, Jackson, Miss.

Missouri.—An examination is required of all who wish to practise medicine or surgery. All persons appearing for examination shall make application, in writing, to the secretary of the Board thirty days before the meeting. They shall furnish satisfactory evidence of their preliminary qualifications, namely: A certificate of graduation from an accredited High School, or State Normal School, College, University, Academy, or a certificate from the County School Commissioner, certifying that they have satisfactorily passed an examination equivalent to a grade from an accredited High School, State Normal School, University, or Academy. They shall also furnish satisfactory evidence of having received a diploma from some reputable Medical College of four years' requirements at the time of graduation: Provided, that the time of graduation has been since March 12, 1901, and two years' requirements, if the date of graduation is prior to March 12, 1901, and shall also furnish evidence of good moral character. The medical examination may be made in whole or in part, in writing, and shall be of elementary and practical character, but sufficiently strict to test the qualifications of the candidate as a practitioner, and shall embrace the subjects of Anatomy, Chemistry, Physiology, Therapeutics, Obstetrics, Gynecology, Surgery, Practice of Medicine, Bacteriology, Medical Jurisprudence and Hygiene, and such other branches as the State Board may direct. In order to pass, an average of 75 per cent. is required. The fee for examination is $15, which entitles the applicant, in case of failure, to reëxamination within one year without paying an additional fee.

Reciprocity is allowed with States having equal requirements, and which similarly recognize this State. Fee, $25.

Secretary of the State Board of Health is Dr. J. A. B. Adcock, Warrensburg, Mo.

Montana.—Every applicant who graduated after 1898, must present evidence of having attended four courses of lectures of at least six months each. Applicants must present a diploma from a legally organized medical school in good standing, and also pass a written examination in the following subjects: Anatomy, Physiology, Materia Medica, Therapeutics, Practice of Medicine, Surgery, Obstetrics, Diseases of Women and Children, Diseases of the Nervous System, Diseases of the Eye and Ear. A general average of 75 per cent. is required in order to pass the examination.

The fee for the examination is $25.

Examinations are held in Helena on the first Tuesday of April and October.

Reciprocity, none.

Secretary of the Board of Medical Examiners is Dr. W. C. Riddell, Helena, Mont.

Nebraska.—Applicants must be of good moral character, and must present a high school diploma or show proof of having taken a college course of at least two years.

Each applicant, if he graduated after August 1, 1898, must show proof that he has attended four full courses of lectures at a recognized medical college, no two courses being in the same year. In case of graduation after August 1, 1891, and prior to August 1, 1898, proof must be given that he has attended three full courses of lectures at a recognized medical college, no two courses being in the same year. And in case of graduation prior to August 1, 1891, proof must be given of having attended two full courses of lectures at a recognized medical college.

No medical school will be recognized by the Board unless said school is recognized by the Association of Medical Colleges of the School of Practice to which it belongs.

Every applicant has to submit to an examination in the following branches: Anatomy, Physiology, Chemistry, Materia Medica and Therapeutics, Practice of Medicine, Surgery, Obstetrics and Diseases of Women, Pathology and such other branches as the Board shall deem advisable.

In order to pass, a general average of 75 per cent. must be obtained. Examinations are held at Lincoln, on the Wednesday after the first Tuesday of February, August, and November; also at end of May. Examination fee is $25; except that for graduates of medical colleges located in Nebraska the fee is only $10.

Reciprocity is permitted with States having requirements of the same standard as those of Nebraska. At present reciprocity exists with: Colorado, District of Columbia, Georgia, Illinois, Indiana, Iowa, Kansas, Kentucky, Louisiana, Maine, Maryland, Michigan, Minnesota, Missouri, Nevada, New Hampshire, New Jersey, Ohio, Oklahoma, Tennessee, Texas, Utah, Virginia, West Virginia, Wisconsin, and Wyoming.

Secretary of the State Board of Health, Dr. E. J. C. Sward, Oakland, Neb.

Nevada.—Applicants for certificates to practise medicine, surgery, or obstetrics in the State of Nevada shall be required to present a diploma from a legally recognized college, and to pass a satisfactory examination before the State Board of Medical Examiners. The examination shall be conducted in the English language, and shall be, in whole or in part, in writing, and shall be on the following subjects, to wit: Anatomy, Physiology, Materia Medica and Therapeutics, Chemistry, Bacteriology, Pathology, Toxicology, Obstetrics, Surgery, General Medicine, Diseases of the Skin, Eye, Ear, Nose, Throat, Brain, Genitourinary system. Examinations shall be practical in character, and designed to discover the applicant's fitness to practise medicine and surgery. In order to pass 75 per cent. must be obtained on each subject.

Fee for the examination is $25.

If an applicant fails in his first examination, he may, after not less than six months, be reëxamined, without additional fee. If he fails in a second examination he shall not thereafter be entitled to another examination in less than one year after the date of second examination, and shall be required to pay for such examination the full fee.

Examinations are held on the first Monday of May and November.

Reciprocity is allowed; the fee is $25. At present Nevada reciprocates with Colorado, Georgia, Illinois, Indiana, Iowa, Kentucky, Louisiana, Maine, Maryland, Michigan, Minnesota, Missouri, Nebraska, New Hampshire, South Carolina, Texas, and Wisconsin.

Secretary of the State Board of Medical Examiners is Dr. S. L. Lee, Carson City, Nev.

New Hampshire.—"The regent shall admit to examination any candidate who pays a fee of $10 and submits satisfactory evidence, verified by oath, if required, that he—(1) Is more than twenty-one years of age; (2) Is of good moral character; (3) Has graduated from a registered college; or satisfactorily completed a full course in a registered academy or high school; or had a preliminary education considered and accepted by the regent as fully equivalent; (4) Has studied medicine not less than four full school years, of at least nine months each, including four satisfactory courses, of at least six months each, in four different calendar years, in a medical college registered as maintaining at the time a satisfactory standard; the regent shall accept, as the equivalent for any part of the third and fourth requirements, evidence of five or more years' reputable practice, provided that such substitution be specified in the license; (5) Has either received the degree of bachelor or doctor of medicine from some registered medical school, or a diploma or license conferring full right to practise medicine in some foreign country."

Examinations are held at Concord, at least twice a year. The subjects for examination are: Anatomy, Physiology and Hygiene, Chemistry, Surgery, Obstetrics, Pathology and Diagnosis, and Therapeutics (including Practice and Materia Medica). The fee for the examination is $10.

If a candidate fails in the examination, he may, after not less than six months' further study, have a second examination without fee.

Reciprocity:—Physicians and surgeons examined and licensed by one of the following boards will be admitted to practice in New Hampshire without further examination, upon payment of fee of $5: Colorado, Georgia, Indiana, Kansas, Kentucky, Maryland, Michigan, Minnesota, Missouri, Nebraska, North Dakota, New Jersey, South Carolina, Tennessee, Vermont, Virginia, West Virginia, Wisconsin, Wyoming.

Any legal practitioner of medicine and surgery in any other State or Territory, which will grant to physicians and surgeons registered in this State similar privileges, will be admitted to practice in this State upon payment of a fee of $10, and upon presentation to the New Hampshire Board of Examiners of evidence satisfactory to them of his professional standing.

Regent of the State Board, H. C. Morrison, Concord, N. H.

New Jersey.—Applicants must be over twenty-one years of age, and of good moral character. They must give proof of having received a satisfactory preliminary academic education, either:—(1) A partial or a complete course in a registered literary college; or

(2) A certificate or diploma issued after four years of study either in a normal, manual training or high school of the first grade, or in a legally constituted academy, seminary, or institute maintaining the same or equivalent academic standards; or

(3) A student's certificate of examination for admission to the freshman class of a registered literary college; or

(4) A certificate of graduation from a foreign institution of learning of recognized standing representing the equivalent of an American high school course of the first grade; or

(5) A certificate from the State Superintendent of Public Instruction of New Jersey who is authorized to determine whether the candidate's academic education prior to beginning the study of medicine was fully equivalent to the standard fixed by law.

Candidates for medical lincense must present their academic credentials to the State Superintendent of Public Instruction, Trenton, N. J., for certification, and the certificates of preliminary academic education issued by him must accompany the applications for admission to the medical examination for State license.

Candidates must have received a diploma conferring the degree of Doctor of Medicine from some legally incorporated medical college (which in the opinion of this board was in good standing at the time of issuing said diploma) in the United States, or a diploma or license conferring the full right to practice all the branches of medicine and surgery in some foreign country, and also have studied medicine not less than four full school years of at least nine months each, including four satisfactory courses of lectures of at least seven months each, in four different calendar years in some legally incorporated American or foreign medical college or colleges, prior to the granting of said diploma or foreign license. Candidates who graduated prior to July 4, 1903, however, and have been in continuous and reputable practice for at least five years since graduation may be admitted to the examinations upon satisfactory evidence of three courses of medical lectures in different calendar years. Candidates who graduated prior to July 4, 1894, and have been in continuous and reputable practice since graduation may be admitted to examination upon satisfactory evidence of two courses of medical lectures in different calendar years.

Examinations are held in Materia Medica and Therapeutics; Obstetrics and Gynecology; Practice of Medicine, including Diseases of the Skin, Nose, and Throat; Surgery, including Surgical Anatomy and Diseases of the Eye, Ear, and Genitourinary Organs; Anatomy; Physiology; Chemistry; Histology, Pathology, and Bacteriology; Hygiene and Medical Jurisprudence. In each of these sections fifteen questions are submitted, of which ten must be answered by the candidate. A total average of the Board in the subjects in which he failed.

The fee for the examination is $25.

Examinations are held at Trenton on the third Tuesday in June and October.

Reciprocity.—With New York after January 1, 1906. New Jersey will now indorse the medical license issued by any State, after examination, whose educational, examining, and licensing requirements are substantially equal to, or higher than those of New Jersey, irrespective of reciprocity, provided the applicant complies with the conditions of indorsement. The fee is $50.

Secretary of the State Board of Medical Examiners, Dr. J. W. Bennett, Long Branch, N. J.

New Mexico.—Any applicant of good moral character who has been in active practice for two years next preceding the date of his application and who is a graduate of a medical college in good standing, after payment of the required fee, will be granted a license without examination. Graduates of colleges in good standing who have not been in active practice for two years and also graduates of reputable medical colleges other than those in good standing, who have served interneships in good hospitals or who have taken six months or more of postgraduate instruction in some institution having ample clinical facilities, or who have had three or more years of actual practice since graduation, may secure license by passing an examination in the following, and such other subjects as the board may from time to time prescribe: Anatomy and Histology, 10 questions; Chemistry, 5 questions; Etiology and Hygiene, 5 questions; Physiology, 5 questions; Materia Medica, 10 questions; Therapeutics, 10 questions; Pathology and Bacteriology, 5 questions; Surgery, 10 questions; Physical Diagnosis, 10 questions; Obstetrics, 10 questions; Gynecology, 5 questions; Practice of Medicine, 10 questions; Medical and Jurisprudence, 5 questions. An average of 75 per cent. must be obtained at such examination by each applicant, and not less than 50 per cent. must be obtained in any one subject; the board shall allow an applicant credit marks of 5 per cent. for five years of active practice. In case of failure in not more than two subjects applicant may be allowed to take another examination at the next regular meeting of the Board in the subjects in which he failed.

The fee for the examination is $25.

Examinations are held in Santa Fe, on the second Monday of January, April, July, and October.

Reciprocity is allowed on conditions equal to those of New Mexico.

Secretary of the Board of Health and Medical Examiners, Dr. J. A. Massie, Santa Fe, New Mexico.

New York.—Each applicant has to submit satisfactory evidence, verified by oath, that he (1) Is more than twenty-one years of age. (2) Is of good moral character. (3) Had prior to beginning the second year of medical study the general education required preliminary to receiving the degree of bachelor or doctor of medicine in this State. (4) Has studied medicine not less than four school years, including four satisfactory courses of at least seven months each, in four different calendar years in a medical school registered as maintaining at the time a standard satisfactory to the Regents.

The regents may, in their discretion, accept as the equivalent for any part of the third and fourth requirement, evidence of five or more years reputable practice, provided that such substitution be specified in the license and as the equivalent of the first year of the fourth requirement evidence of graduation from a registered college course, provided that such college course shall have included not less than the minimum requirements prescribed by the regents for such admission. (5) Evidence that applicant has either received the degree of bachelor or doctor of medicine from some registered medical school, or has a diploma or license conferring full right to practise medicine in some foreign country. Candidates must also pass an examination in:—(1) Anatomy; (2) Physiology; (3) Hygiene and Sanitation; (4) Chemistry; (5) Surgery; (6) Obstetrics and Gynecology; (7) Pathology and Bacteriology: (8) Diagnosis.

The Regents may also in their discretion admit conditionally to the examination in anatomy, physiology, hygiene, sanitation, and chemistry, applicants 19 years of age certified as having studied medicine not less than two years, including two satisfactory courses of at least seven months each, in two different calendar years, in a medical school registered as maintaining at the time a satisfactory standard, provided that such applicants meet the second and third requirements.

Each paper has fifteen questions, and of these the applicant selects ten.

Seventy-five per cent. in each topic is required for a license. "Candidates must pass at 90 per cent. or more in each of the eight topics in order to receive an honor license."

The fee for examination is $25.

The examination may be omitted in the case of physicians who "have reached a position of conceded eminence and authority in the profession."

Examinations are held at New York, Albany, Syracuse, and Buffalo, in January, May, June, and September.

Reciprocity exists under certain conditions with Michigan, New Jersey, Ohio, and Vermont.

Secretary of the Regents of the University of New York, Dr. C. F. Wheelock, University of State of New York, Albany, N. Y.

North Carolina.—Applicants must present a certificate of good moral character from two persons known to the board. "All applicants shall exhibit a diploma, or furnish satisfactory proof of graduation from a medical college in good standing requiring an attendance of not less than three years and supplying such facilities for clinical instruction as shall meet the approval of the board. But license or other satisfactory evidence of standing as a legal practitioner in another State shall be accepted in lieu of a diploma, and entitle to examination." Applicants must, further, be examined in the following subjects: Anatomy, Physiology, Surgery, Pathology, Medical Hygiene, Chemistry, Pharmacy, Materia Medica, Therapeutics, Obstetrics, and the Practice of Medicine. To secure a license an average grade of not less than 80 per cent. will be required, but an applicant receiving a grade of 35 per cent. or less in any one branch shall be rejected regardless of his grade in other branches.

The fee for the examination is $10, which shall be returned in the event of the applicant's rejection.

Reciprocity is allowed; but

1. The applicant must have a diploma from a medical college requiring a three years' course of study for such degree.

2. He must have license from a State Board of Examiners requiring the same per cent. as this State, which is 80.

3. He must present a sworn affidavit from two practising physicians as to his professional standing in his community, the burden of proof resting upon the applicant.

4. He shall attend the meeting of the Board at the time of application and make the same in person.

5. He shall pay a fee of ten dollars for such license.

6. He must not have failed before the North Carolina Board.

7. He must have been in actual practise for five years in the State from which he comes.

Secretary of the Board of Medical Examiners is Dr. B. K. Hays, Oxford, N. C.

North Dakota.—From all graduates of 1905 and thereafter a minimum entrance requirement of graduation from an accredited high school or its equivalent is demanded. All applicants must present evidence of having graduated from a reputable medical college and attended three courses of lectures of at least six months each; provided, however, that after the year 1904, applicants must present evidence of having graduated from a reputable college, and attended four courses of lectures of at least eight months each.

Applicants must further pass an examination in the following branches: Anatomy, Physiology, Chemistry, Pathology, Therapeutics, Diseases of Women and Children, Nervous Diseases, Diseases of the Eye and Ear, Medical Jurisprudence, and such other branches as the Board deems advisable. The Board shall cause such examination to be practical and scientific and sufficient to test the candidate's fitness to practise medicine, surgery, and obstetrics. A general average of 75 per cent. is required to pass, and an applicant must not fall below 65 per cent. in any branch. The fee for the examination is $20.

Examinations are in writing, and are held at Grand Forks, on the first Tuesday in January, April, July, and October.

Reciprocity. Under certain conditions and upon licenses bearing the date of July 1, 1905, or later, and secured by examination, North Dakota reciprocates with the following States: Maine, Vermont, Michigan, Illinois, Wisconsin, West Virginia, Wyoming, Minnesota, and Texas.

Secretary of the State Board of Medical Examiners, Dr. H. M. Wheeler, Grand Forks, N. D.

Ohio.—Applicants must furnish satisfactory proof of being more than twenty-one years of age and of good moral character. They must also give evidence of preliminary education as follows:—(1) A diploma from a reputable college granting the degree of A.B., B.S., or equivalent degree; or (2) a diploma from a legally constituted normal school, high school, or seminary, issued after four years study; or (3) a teacher's permanent or life certificate; or (4) a student's certificate of examination for admission to the freshman class of a reputable literary or scientific college.

In the absence of the foregoing qualifications the entrance examiner may examine the applicant in such branches as are required for graduation from a first-class high school of this State, and to pass such examination shall be sufficient qualification.

Applicants must further show that they are graduates in medicine from some legally chartered medical college in the United States, in good standing. Applicants will then have to pass an examination in the following subjects: Anatomy, Physiology, Pathology, Chemistry, Materia Medica and Therapeutics, Surgery, the Principles and Practice of Medicine, Obstetrics, Diseases of Women and Children, and Physical Diagnosis, and such other subjects as the Board requires.

The fee for the examination is $25; in case of failure, another examination may be taken within one year without payment of additional fee.

Examinations are held on the second Tuesday of June and December, at Columbus, and sometimes also at Cincinnati and Cleveland.

Reciprocity with Illinois, New Jersey, New York and Texas upon the basis of examination only; also under certain conditions with Colorado, District of Columbia, Indiana, Iowa, Maine, Maryland, Michigan, Minnesota, Nebraska, Vermont, and Wisconsin.

Secretary of the State Board of Medical Registration and Examination, Dr. G. H. Matson, Columbus, Ohio.

Oklahoma.—Every applicant must submit proof of good moral character, and two unmounted photographs. He must also present a diploma issued by some legally chartered medical school or college, the requirements of which medical school or college shall have been at the time of granting such diploma in no particular less than those prescribed by the American Association of Medical Colleges, or the Southern Association of Medical Colleges in that year in which the diploma was granted. Or he must show satisfactory evidence of having possessed such diploma or license from some legally constituted institution which grants medical and surgical licenses only on actual examinations, or satisfactory evidence of having possessed such license or diploma.

Candidates will be examined on the following subjects: Anatomy, Physiology, Chemistry, Hygiene, Pathology, Physical Diagnosis, Obstetrics, Gynecology, Medical Jurisprudence, Surgery, Bacteriology, Histology, Theory and Practice, Materia Medica and Therapeutics. There will be ten questions on each of the above subjects. The Board may add other subjects whenever it deems it necessary to test the applicant's qualifications, and to keep abreast with medical progress.

Candidates must make an average of not less than 70 per cent., and not less than 50 per cent. on any branch.

The examination fee is $15. Candidates who fail may take another examination within one year without additional fee.

The regular meeting of the Board will be held on the second Tuesday in January, April, July, and October at Guthrie, unless otherwise ordered by the Board.

Reciprocity, none.

Secretary of State Board of Medical Examiners, Dr. Frank P. Davis, Enid, Oklahoma.

Oregon.—Applicants must be "of good repute," must make application stating time spent in study of medicine, place of study, and time and place of actual practice. Applicants must also pass an examination in the following branches: Anatomy, Physiology, Chemistry, Materia Medica, Therapeutics, Practice of Medicine, Surgery, Obstetrics, Diseases of Women, Medical Jurisprudence, and such other branches as the Board shall deem advisable. Such examinations shall be both scientific and practical, and of sufficient severity to test the candidate's fitness to practise medicine and surgery, and shall be by written or printed (or partly written or partly printed), questions and answers. The fee for the examination is $10.

Examinations are held at Portland, Oregon, on the first Tuesday of January and July.

Reciprocity, none.

Secretary of Board of Medical Examiners, Dr. Byron E. Miller, Portland, Oregon.

Pennsylvania.—Applicants must present satisfactory evidence of being more than twenty-one years of age, and of good moral character. Applicants must show that they have received competent preliminary education as follows: (a) A diploma of a literary or scientific college, a State normal

school, a high school having a course of not less than three years, or an academy having an approved high school standing. (b) A teacher's permanent certificate issued by the school department of Pennsylvania. (c) The certificate of a legally authorized State Examining Board covering required subjects. (d) A certificate showing three years' completed work in an approved high school, officially signed and sealed by the principal or other authorized officer. (e) In lieu of any of the above, an equivalent examination. Applicants must also have received a diploma conferring a degree in medicine from a legally incorporated medical college of the United States, or a diploma or license conferring the full right to practise all the branches of medicine and surgery in some foreign country.

Applicants must also pass an examination in Anatomy; Physiology and Pathology; Chemistry and Materia Medica; Surgery; Obstetrics; Diagnosis and Hygiene; Therapeutics and Practice of Medicine.

A general average of not less than seventy-five points is necessary. No license shall be issued to any candidate whose examination papers shall, on any two subjects, fall below fifty-five; provided, that those papers marked below fifty-five shall be subject to revision by the entire Board by which the candidate was examined. The fee for the examination is $25; and in case of failure a reëxamination can be taken after six months and before two years without payment of additional fee.

Examinations are held twice a year in Philadelphia and Pittsburg, in June and December.

Reciprocity, none.

Secretary of the Medical Council, N. C. Schaeffer, Harrisburg, Pa.

Rhode Island.—Applicants must be graduates from a medical school in good standing, and must pass an examination as follows: "Examinations shall be in writing and in English, and of a practical character, but sufficiently strict to test the qualifications of the applicant as a practitioner. Examinations will be presented upon the following subjects or groups of subjects: (1) Anatomy and Physiology; (2) Materia Medica and Chemistry; (3) Pathology; (4) Surgery; (5) Theory and Practice; (6) Obstetrics and Gynecology; (7) Hygiene and Medical Jurisprudence. Ten questions will be presented upon each subject or group of subjects. An average of 80 per cent. of correct answers will be required." The fee for the examination is $10, and for the certificate (if issued) $2.

Examinations are held in Providence, on the first Thursday in January, April, July, and October.

Reciprocity, none.

Secretary of the State Board of Health, Dr. Gardner T. Swarts, Providence, R. I.

South Carolina.—Every applicant (1) must be twenty-one years of age; (2) must exhibit a diploma from a medical college of established reputation; (3) must present a certificate of good moral character and sobriety from at least two reputable persons known to the Board, and (4) must give evidence of sufficient preliminary education (equivalent to the possession of a teacher's first grade certificate). No person who shall have graduated after February 27, 1904, shall be eligible for examination before this Board, unless he or she shall give evidence in addition to the other requirements that he or she has attended *four* full courses of lectures of at least twenty-six weeks each, no two courses being in the same year, and has received a diploma of M.D. therefrom.

The examination is conducted in writing, and is divided into two sections:—the first, or Junior Curriculum, comprising:—1. General Anatomy. 2. Physiology and Histology. 3. Materia Medica and Medical Botany. 4. Chemistry, Organic and Inorganic, and Medical Physics. 5. Bacteriology and Pathology.

The second, or Senior Curriculum, comprises:—1. Anatomy, Regional and Surgical. 2. Practical Hygiene and Sanitary Science, State Medicine. 3. Practical Uranalysis, Urinary Microscopy. 4. Therapeutics and Toxicology. 5. Surgery, General and Special, Surgical Procedure. 6. Practical Medicine and Diseases of Children. 7. Practical Obstetrics and Gynecology. 8. Medical Jurisprudence.

All applicants before the Board, holding a diploma from a four-years' graded medical college of established reputation, who have pursued a study of four separate courses, and have attained a mark of not less than 75 per cent. on each individual branch of their curriculum, as evidenced by a certificate from the Dean of their college, will be exempted from examination in the Junior Curriculum.

The standard required by the State Board of Medical Examiners shall be an average of not less than 75 per cent. on all the branches examined upon, and not less than 60 per cent. on any individual branch.

Examination fee, $10.

Examinations are held once a year, at Columbia, on the second Tuesday in June.

Reciprocity exists under certain conditions with: Illinois, Kansas, Maine, Maryland, Michigan, Minnesota, Missouri, Nevada, Texas, Utah, Virginia, West Virginia, Wisconsin, and Wyoming. Fee, $10.

Secretary of State Board of Medical Examiners, Dr. H. H. Wyman, Aiken, S. C.

South Dakota.—Applicants must give satisfactory proofs of being at least twenty-one years of age, and of good moral character; also a recent unmounted photograph with signature and affidavit. Applicants must also present evidence of having attended four full courses of lectures, of at least twenty-six weeks each in a legally organized and reputable medical college, recognized by the Board of Medical Examiners, no two courses being in the same year; and of having received a diploma from a legally organized and reputable medical college, which shall be in good standing as shall be determined by the Board, and said diploma must be submitted to the Board for inspection and verification; provided that the four courses of lectures of six months each shall not apply to applicants who graduated prior to 1898.

The Board, in its classification of diplomas, will recognize only such medical colleges as require as a condition of admission the equivalent, at least, of a standard high school education, in addition to the full four years' attendance in medical college. After 1910 this requirement will be at least one year in a college of liberal arts, or its equivalent.

Applicants must also pass an examination in the following subjects: Anatomy, Physiology, Chemistry, Pathology, Therapeutics, Practice of Medicine, Surgery, Obstetrics, Gynecology, Diseases of the Eye and Ear, Bacteriology, Medical Jurisprudence, and such other branches as the board may deem advisable.

Ninety questions are given, on twelve principal

subjects, and a general average of 75 per cent. of correct answers is required to pass. The fee for examination is $20. Candidates who fail to pass the examination are entitled to a second trial without extra cost.

Examinations are held twice a year, on the second Wednesday of January and July, at places determined by the board.

Reciprocity, none.

Secretary of Board of Medical Examiners, Dr. H. E. McNutt, Aberdeen, S. D.

Tennessee.*—Applicants must be of good moral character; no diploma is required. Every applicant must take the medical examination. "In examining the written answers of the applicants (in the medical examination), the evidences of an English education as shown in the papers shall be considered in determining the fitness of an applicant for license to practise medicine in this State." Examinations shall be both written and oral, and upon the following branches: Anatomy, Physiology, Chemistry, Pathology, Surgery, Obstetrics, Materia Medica, and Practice. Candidates must obtain 75 per cent. in order to pass. The fee for the examination is $10.

Examinations are held once a year in Nashville, in May.

Reciprocity is allowed with such States as will recognize the Tennessee certificate.

Secretary of the State Board of Medical Examiners, Dr. T. J. Happel, Trenton, Tenn.

Texas.—Every applicant must submit satisfactory evidence of being more than twenty-one years of age, of good moral character, and a graduate of a reputable medical college. The applicant must then take an examination in the following branches: Anatomy, Physiology, Chemistry, Histology, Pathology, Bacteriology, Physical Diagnosis, Surgery, Obstetrics, Gynecology, Hygiene, and Medical Jurisprudence.

Ten questions are set on each of these subjects. In order to pass the examination a general average of 75 per cent. is required.

The examination fee is $15.

Reciprocity is allowed by law with other States and Territories having requirements equal to those of Texas. The fee is $20.

The following States are now in reciprocal relation with Texas: Missouri, Maine, Nebraska, Minnesota, Michigan, Kentucky, Illinois, Indiana, Iowa, District of Columbia, West Virginia, Maryland, Wisconsin, Vermont, North Dakota, Ohio, and Virginia.

Secretary of the State Board of Medical Examiners, Dr. C. B. Foscue, Waco, Texas.

Utah.—Applicants must have received a certificate from a first grade high school, or its equivalent, and also a degree or diploma from a chartered medical college, in good standing, and must also pass an examination. A recent unmounted photograph is also required. The subjects for examination are: Histology, Anatomy, Physiology, Chemistry, Toxicology, Urinalysis, Materia Medica, Therapeutics, Bacteriology, Pathology, Theory and Practice of Medicine, Surgery, Obstetrics, Gynecology, Pediatrics, Dermatology, Hygiene, Medical Jurisprudence, Ophthalmology, Otology, Rhinology, Laryngology, and such other branches as the Board shall direct. An average of 75 per cent. is required. The fee for the examination is $15.

*Legislation is now pending, and may change the requirements.

Examinations are held at Salt Lake City on the first Monday in January, April, July, and October.

Reciprocity exists under certain conditions with: Missouri, Maine, Minnesota, Michigan, Indiana, Georgia, Kansas, Wisconsin, South Carolina, Iowa, Illinois, Colorado, Nebraska, Tennessee, Wyoming, New Jersey, and Kentucky. Fee, $25. "The applicant for reciprocity must have been engaged in reputable practice of medicine in the State from which he comes at least one year before his certificate will be accepted by the Utah board."

Secretary of the Board of Medical Examiners, Dr. R. W. Fisher, Salt Lake City, Utah.

Vermont.—A person twenty-one years of age and of good moral character, who is a graduate of a legally chartered medical college or university, having power to confer degrees in medicine and surgery, and such medical college or university being recognized as determined by the Board, shall, upon payment of a fee of twenty dollars, be entitled to examination, and, if found qualified, shall be licensed to practise medicine and surgery in this State.

By a rule of the Board applicants for examination shall present documentary evidence showing that they are graduates of an accredited high school maintaining a four year course, or its value in counts obtained by an examination in subjects of high school grade or a New York Medical Student's Regent's certificate.

The examination shall be wholly or in part in writing, in the English language, and shall be of a practical character, sufficiently strict to test the qualification of the applicant. It shall embrace the general subjects of Anatomy, Physiology, Chemistry, Pathology, Bacteriology, Hygiene, Practice of Medicine, Surgery, Obstetrics, Gynecology, Materia Medica, Therapeutics and Legal Medicine. Each applicant shall pass a general average of 75 per cent. to entitle him to a license; provided, however, that reputable practitioners may be allowed one per cent. for each year of practice, but such allowance shall not exceed ten per cent.

"In order to receive consideration, examination papers must be legibly written in English and free from such errors in spelling, grammar, and reasoning, as would show gross ignorance of the elementary branches of education."

Examination fee is $20.

Examinations are held in Montpelier on the second Tuesday in January, and in Burlington on the second Tuesday in July.

Reciprocity arrangements have been entered into with the States of Illinois, Indiana, Maine, Michigan, Maryland, New Hampshire, New York, New Jersey, North Dakota, Ohio, Texas, Wisconsin, Wyoming, and the District of Columbia on certificates obtained by examination and whose standard of requirements is equal to that of Vermont.

Secretary of State Board of Medical Registration, Dr. W. Scott Nay, Underhill, Vt.

Virginia.—Applicants must present their diplomas from some recognized medical college, chartered by the State or Territory in which it is situated. Applicants must also pass an examination.

The examination comprises the following subjects: Chemistry, Toxicology and Medical Jurisprudence; Laryngology, Rhinology, Ophthalmology and Otology; Anatomy and Embryology; Histology, Physiology and Hygiene; Pathology, Bacteriology and Neurology; Obstetrics, Gynecology and Pediatrics; Materia Medica and Therapeutics; Practice

of Medicine, Diagnosis and Etiology; Surgery.

A total average of 75 per cent. shall be necessary to license a candidate (he or she having otherwise complied with the law); provided, that in no one section shall the percentage be less than 45 per cent.; if so, the candidate shall be rejected, regardless of the total average.

Physicians who have been in active practice legally for over five years, graduates from reputable colleges, are granted oral examinations.

The fee for the examination is $10; those failing to pass the examination will not be required to pay further fee when they appear for reexamination.

Examinations are generally held in June and December.

Reciprocity exists under certain conditions.

At present the Medical Examining Board of Virginia reciprocates in medical licenses with the following States since June, 1904: Indiana, Georgia, Michigan, Nebraska, Delaware, Maryland, South Carolina, Texas, Wisconsin, and District of Columbia.

Reciprocity with West Virginia, Minnesota, New Hampshire, Missouri, and Kentucky, since June, 1907. Maine, since December, 1907. Wyoming, since June, 1908.

Secretary of Medical Examining Board, Dr. R. S. Martin, Stuart, Va.

Washington.—Applicants must be over twenty-one years of age, must present a written recommendation of good moral and professional character from two physicians in good standing, and must have graduated from some duly authorized and recognized medical college now having at least a four years' graded course. An unmounted photograph must accompany the application; and the applicant's diploma must be exhibited to the secretary.

The examinations will be in writing covering the following subjects, which are so grouped that 100 questions will be the total asked:—Anatomy and Physiology, 15 questions; Histology, Pathology and Bacteriology, 10 questions; Surgery, 10 questions; Toxicology and Chemistry, 10 questions; Preventive Medicine and Medical Jurisprudence, 10 questions; Practice of Medicine and Diseases of Children, 15 questions; Obstetrics and Diseases of Women, 10 questions; Diseases of Eye and Ear and Nervous Diseases, 10 questions; Materia Medica and Therapeutics, 10 questions.

Evidence of the applicant's lack of knowledge of correct language, as derived from his written answers to questions, will militate against him.

Licenses will be issued to those who make a general average of 75 per cent., excepting in the case of physicians of ten years' practice, in which case the required grade is 70 per cent., provided all the requirements of this board are satisfactorily complied with.

Examination fee is $25.

Examinations are held on the first Tuesday of January and July.

Reciprocity, none.

Secretary of the State Medical Examining Board is Dr. K. Turner, Seattle, Wash.

West Virginia.—Every applicant must be a graduate of a reputable medical college, recognized as such by the State Board of Health, and must also pass an examination. At such examinations, written and oral questions shall be submitted to the applicants for license, covering all the essential branches of the sciences of medicine and surgery, and the examination shall be a thorough and decisive test of the knowledge and ability of the applicants. During the past year the examinations embraced the following subjects: Anatomy and Embryology; Physiology and Histology; Chemistry and Medical Jurisprudence; Materia Medica and Therapeutics; Bacteriology and Hygiene; Practice and Pediatrics; Obstetrics and Gynecology; Surgery, and Special Practice (including Physical Diagnosis, Throat, Nose, Eye, and Nervous Diseases).

A general average of 80 per cent. is required, with not less than 65 per cent. on any subject.

The fee for examination is $10; in case of failure, the candidate can be reexamined within one year without additional fee.

Examinations are held not less than three times a year, at places convenient to applicants, or to the Board of Health.

Reciprocity: "The State Board of Health may accept in lieu of an examination, the certificate of license to practise medicine legally granted by the board of registration or examination or licensing board of any other State, Territory, or any foreign country whose standard of qualification for the practice of medicine is equivalent to that of this State, and grant to the said applicant a certificate of license to practise medicine in this State; *Provided*, such States, Territories, or foreign countries accord like privilege to medical licentiates of this State."

Secretary of the State Board of Health, Dr. Hugh A. Barbee, Point Pleasant, W. Va.

Wisconsin.—All applicants must present evidence of good moral character; also a diploma from a reputable medical college requiring a four years' course of at least seven months each before graduation, no two of such courses to be taken within any one twelve months, and that shall require for admission thereto a preliminary education equivalent to that necessary for entrance to the junior class of an accredited high school in this State, including a one year's course in Latin, and that shall, after the year 1906, require for admission to such school a preliminary education equivalent to graduation from an accredited high school of this State. Applicants must also pass an examination in Pathology, Surgery, Obstetrics, Gynecology, Anatomy, Materia Medica, and Therapeutics, Practice of Medicine, Dietetics, Jurisprudence, Physiology, Hygiene, Diagnosis, Toxicology, Histology, Bacteriology, Chemistry, Uranalysis, Neurology, Pediatrics, Laryngology, and Ophthalmology. "A general average of 75 per cent. shall be necessary, provided that in no one branch shall the percentage be less than 60." The fee for the examination and license is $20. If license is not granted, $5 will be returned to the applicant.

Regular meetings are held on the second Tuesday of January, at Milwaukee; and on the second Tuesday of July, at Madison.

Reciprocity: Graduates of reputable medical colleges with a certificate from any State Board whose requirements are equal to those of this State, may be admitted to practise without examination at the discretion of the Board. Fee, $25.

Secretary of the Board of Medical Examiners, Dr. J. V. Stevens, Jefferson, Wis.

Wyoming.—The applicant must be a graduate from a regularly chartered college of the system which he claims to practise. Said college must be recognized by the State Board of Health or the State Board of Medical Examiners of the State in

which it is located. He shall give evidence of the fact that he is a person of good moral character. He shall present his diploma to the State Board of Medical Examiners for verification as to its genuineness. He shall appear before the State Board of Medical Examiners in person at a time and place appointed, and shall pass an examination sufficiently strict to test his qualifications as a practitioner. Said examination may be in whole or in part in writing. It shall be of an elementary and practical character, and shall be upon the following subjects: Anatomy, Physiology, Chemistry and Toxicology, Pathology, Physical Diagnosis, Gynecology, the principles of Surgery, Obstetrics, Hygiene, and Bacteriology. He shall further be required to pass an examination in such branches as are necessary to complete the system of which he is a practitioner. An average grade of 75 per cent. in all branches of the examination shall be required; provided, that the applicant shall not pass lower than 60 per cent. in any one branch.

The fee for examination is $25. Should the applicant fail to pass, he may present himself for re-examination within one year without the payment of an additional fee.

Reciprocity is allowed by law with States having similar requirements, and which recognize the licenses issued by this Board.

Secretary of the State Board of Medical Examiners, Dr. S. B. Miller, Laramie, Wyo.

Dominion of Canada.

Alberta.—Any person who shall produce a diploma of qualification from any College or School of Medicine and Surgery, which exacts for such diplomas attendance on at least a four years' course of lectures of at least six months each, evidence of which shall be produced if required, and who shall furnish to the Council satisfactory evidence of identification, and pass a satisfactory examination, and shall pay the examination fee of $50, can register on payment of a further fee of $52.

The subjects of examination are: Anatomy, Chemistry, Physiology and Histology, Materia Medica and Therapeutics, Pathology and Bacteriology, Sanitary Science, Medical Jurisprudence, Practice of Medicine, Surgery, Diseases of Women and Children, and Obstetrics. The examinations are written and oral.

Examinations are held on the first Tuesday in August, at Calgary, Alberta.

Registrar and Treasurer, Dr. J. D. Lafferty, Calgary, Alberta.

British Columbia.—The Council of the College of Physicians and Surgeons of British Columbia shall admit upon the register any person who shall produce from any college or school of medicine and surgery, requiring at least four years' course of study, a diploma of qualification, provided that where the college or school of medicine did not require a course of study of at least four years, but a post-graduate course has been taken, which in point of time, added to the college of school of medicine course, completes a period of four years, it shall be deemed sufficient; provided, also, that the applicant shall furnish to the Council satisfactory evidence of identification, and pass a satisfactory examination touching his fitness and capacity to practise as a physician and surgeon.

Candidates must produce satisfactory proof that they have actually taken and attended a four years' course of medical lectures.

The examination shall be orally and in writing, upon the following subjects: Anatomy; Chemistry and Public Health; Physiology and Histology; Materia Medica and Therapeutics; Medical Jurisprudence; Theory and Practice of Medicine and Medical Pathology; Theory and Practice of Surgery and Surgical Pathology; Clinical Medicine; Clinical Surgery and Surgical Anatomy; Obstetrics and Diseases of Women and Children; Urinary Analysis and Clinical Microscopy.

Before examination, the candidate shall pay to the Registrar of the College the fee of $100 for the examination, $50 of which shall be returned if the candidate be rejected.

There are two examinations each year, beginning on the first Monday of May and the last Monday of October. All examinations are held at the college rooms, in the New Parliament Buildings, Victoria.

For more particular information apply to the Registrar, Dr. C. J. Fagan, Victoria, B. C.

Manitoba.—The College of Physicians and Surgeons is the sole licensing body in medicine in the province, and the University of Manitoba is the sole examining body.

If the applicant for license be a graduate in medicine from any university in the United States, he shall be required, in addition to sending his degree (or diploma), to furnish complete detailed and authoritative information as follows: (1) As to his matriculation; giving the name and address of the institution in which he was examined, the subjects, and the extent of each required. (2) As to medical course; the number and length of sessions, subjects taught, number of courses in each, and number of lectures in each course, amount of clinical instruction in the different courses, etc., etc.

On receipt of this information the university will decide as to the eligibility or otherwise of the applicant to write for license.

Each applicant, at the same time that he sends his credentials to the Registrar of the C.P.S., should send $15 examination fee in a separate communication addressed to Mr. D. M. Duncan, Registrar of the University, which will be returned to him in case he is not permitted to write.

The subjects of examination for license are: *Written:* Medicine, Surgery, Obstetrics and Diseases of Children, Gynecology, Materia Medica and Therapeutics. *Oral:* Clinical Medicine, Clinical Surgery, Clinical Ophthalmology and Otology. A percentage of 50 is required in each to pass.

A candidate failing in three or more subjects must write on the whole examination again, and can only do so at a subsequent regular spring examination. If he fail in two subjects, or less, he will be required to write on these only, and may do so at the time of the Supplemental Examinations in September, or at the next spring examination.

Examinations are held annually, on the third Monday in April.

The fee for license, $75, is payable immediately after the receipt by the Registrar of the C.P.S. of the report of the university examinations.

Registrar C.P.S., Manitoba, J. S. Gray, M.D., 358 Hargrave Street, Winnipeg, Manitoba

New Brunswick.—No person shall be entitled to have his name entered on the Register of the Council, or to receive a license to practise from such Council, unless he shall satisfy the Council that he has passed the matriculation or preliminary examination; that after passing such examination, he has followed his studies during a period of not less than

four years; that during such four years he has attended at some university, college, or incorporated school of medicine in good standing, a graded collegiate course of four sessions of not less than six months each; that previous to graduation or obtaining a diploma he has passed satisfactory examinations in the subjects of the curriculum, and that the examinations have been conducted, and the diploma granted, by a medical school, college, university, or licensing body, which itself requires a four years' graded course, as above appointed; and in case he has such degree or diploma that he has passed such examination as to his knowledge and skill for the efficient practice of his profession as may be prescribed by the Council; that he is not less than twenty-one years of age; that he has paid to the Registrar of the Council a fee of $10.

Each and every person who may hereafter apply for registration under the New Brunswick Medical Act, 1881, and amending acts, and to have his name entered upon the register of the said Council, shall, whether or not he has a degree or diploma, pass a satisfactory examination, both written and oral, before examiners to be appointed by the said Council, in the following subjects: Anatomy; Chemistry; Physiology and Histology; Materia Medica, Pharmacy and Therapeutics; Practice of Medicine, including Clinical Medicine; Surgery, including Clinical Surgery, and Diseases of Eye and Ear; Obstetrics and Diseases of Women and Children; Medical Jurisprudence and Toxicology and Hygiene; Pathology, including Bacteriology.

The professional examinations will be held in St. John twice each year, commencing on the fourth Wednesday in June, and on the second Wednesday in December.

Registrar of the Council of Physicians and Surgeons, Dr. Stewart Skinner, St. John, New Brunswick.

Nova Scotia.—Every student must spend a period of at least four academic years in actual professional study subsequent to his having passed the preliminary or matriculation examination and being registered as a medical student; and the prescribed period of study shall include four collegiate sessions of at least eight months' duration, or an equivalent, each year.

All persons beginning the study of medicine after July 1, 1908, will be required to complete a course of at least five years, including five collegiate sessions of eight months' duration (or equivalent) each year.

Candidates for the license of this Board will be required, subsequent to their registration as medical students, to pass three examinations, to be known as the First, Second, and Third Professional Examinations.

These examinations will be held twice during the year. The Third or Final Professional will begin on the second Wednesday in April, and on the first Wednesday in September.

Until further notice, any candidate who produces to the Registrar satisfactory certificates of having passed in the subjects of the First and Second Professional Examinations at any medical college or university recognized by the Board, will be exempt from further examination in such subjects.

The First Professional Examination will embrace the following subjects, viz., Physics, Chemistry, Anatomy, Physiology, including Histology. The fee payable for admission to this examination shall be $20; for reentry in all subjects after rejection, $15; for reentry in one or more subjects after obtaining a pass in the others in virtue of Section 20, $5 for each subject.

The Second Professional Examination will include Pathology and Bacteriology, Materia Medica and Pharmacy. The fee payable for admission to this examination shall be $15; for reentry in both subjects after rejection, $10; for reentry in one subject after pass in the other, $5.

The Third Professional Examination shall embrace the following subjects: Medicine, including Therapeutics and Medical Anatomy; Clinical Medicine; Surgery, including Surgical Anatomy and Diseases and Injuries of the Eye, Ear, Throat; Clinical Surgery; Obstetrics and Diseases of Women and of New-born Children; Medical Jurisprudence and Hygiene.

All candidates will be subjected, in addition to the written and oral examinations, to practical clinical examinations in Medicine and Surgery which will include the Examination of Patients, Physical Diagnosis, the Use of the Microscope, Pathology of the Urine, Surgical Appliances, Bandages, Surface Markings, etc.

In case of failure, a candidate who obtains 60 per cent. in any subject or subjects, will, on reexamination, be exempted in such subject or subjects, but will be required to obtain 60 per cent. in each of the remaining subjects.

For candidates who have paid for the First and Second Professional Examinations, the fee payable for admission to the Final Examination shall be $35; for reentry in all subjects after rejection, $25; for reentry in one or more subjects after passing in the others, $5 for each subject.

Secretary and Registrar of the Medical Board, Dr. A. W. H. Lindsay, 241 Pleasant Street, Halifax, Nova Scotia.

Ontario.—Every legally qualified medical practitioner in this province is a member of the College of Physicians and Surgeons of Ontario, and must pass a satisfactory examination before the same.

The Council has power and authority to fix the terms upon which practitioners of medicine, duly qualified in other countries, may be admitted as members of the College of Physicians and Surgeons of Ontario, this being the only mode in which they can become legally entitled to practise their profession in this province.

Proper credentials of satisfactory preliminary education must be presented. Further, every student must have spent a period of five years in actual professional studies, the prescribed period of studies to include four winter sessions of eight months each. The fifth, or final year, to be devoted to clinical work.

Graduates in medicine from recognized colleges outside the Dominion of Canada, who desire to qualify themselves for registration, must pass the matriculation required by the Council; and must attend one or more full winter course of lectures in one of the Ontario medical schools and must complete fully the practical and clinical curriculum required by the Council after the fourth year, and shall pass before the examiners appointed by the Council all the examinations hereinafter prescribed, so as to complete fully the curriculum.

All applicants must also pass the professional examinations required. These examinations are divided into three parts: *Primary*, *Intermediate* and *Final*. The *Primary* examination includes: (*a*) Anatomy; (*b*) Physiology and Histology; (*c*)

Chemistry (Theoretical and Practical); and (*d*) Materia Medica and Pharmacy. The *Intermediate* examination includes: (*a*) Medical, Surgical, and Topographical Anatomy; (*b*) Principles and Practice of Medicine; (*c*) General Pathology and Bacteriology; (*d*) Surgery, other than operative; (*e*) Operative Surgery; (*f*) Midwifery, other than operative; (*g*) Operative Midwifery; (*h*) Medical Jurisprudence, including Toxicology and Mental Diseases; (*i*) Sanitary Science; (*j*) Diseases of Children; (*k*) Diseases of Women, and (*l*) Therapeutics. The *Final* examination includes; (*a*) Clinical Medicine; (*b*) Clinical Surgery; (*c*) Diseases of Women, and (*d*) Diseases of Children, Medical and Surgical. In these examinations 50 per cent. is required to pass, and 75 per cent. for honors. The Primary and Intermediate examinations shall be written and oral; the Final, oral and clinical.

The fees are: For matriculation, $20; Primary examination, $30; Intermediate and Final, including registration, $50. Candidates who have failed in any professional examination in more than one subject shall pay a fee of $20 for each subsequent examination; if only one subject, $10.

Examinations are held in May and September.

Registrar of the College of P. and S. of Ontario, Dr. John L. Bray, Toronto, Ontario.

Prince Edward Island.—Applicants must have passed a matriculation examination satisfactory to the Council. They must also prove attendance during four years at a university, college, or incorporated school of medicine in good standing, upon a graded collegiate course of four sessions of not less than eight months each.

No candidate shall be admitted to the professional examination unless at least fourteen days before such examination he shall have made a written application to the registrar, in a form prescribed by the Council, and shall have produced before the registrar all required certificates, and before such examination shall have paid to the registrar the required fee for such examination, also the fee for registration, which latter fee shall be refunded in the event of failure to pass the examination. All applications shall be submitted to the Council by the registrar, and shall be subject to its approval.

The examinations take place in the months of July and October in each year, at such time and place as the president shall appoint.

In order to pass, candidates must make 50 per cent. of the marks in each subject.

If 50 per cent. be made in all the subjects but one, he may present himself for examination in this subject alone, with or without additional fee, as the Council shall decide.

The fee for the professional examination is $15; and for registration $20.

Quebec.—Every person, possessing or who shall obtain a medical degree or diploma from any university, college, or medical school mentioned in article 3073 of the Revised Statutes of the Province of Quebec, shall be entitled to such license without examination, provided such diploma be obtained, only after, at least, four years of medical studies, from the date of admission to study, and provided his examinations have been passed in presence of the assessors, according to the requirements of the law. The Provincial Medical Board shall always oblige foreign candidates to undergo the professional examination.

No one shall be entitled to the license of the college on the mere presentation of a diploma, unless he has been previously admitted to the study of medicine in accordance with the provisions of the law, or unless he has passed, at least four years previously, an equivalent preliminary examination, before a college, a school, or a Board authorized by law in His Majesty's possessions, outside the Province of Quebec.

The duration of the medical studies fixed at four years, by this and the preceding article, shall be of five years, as soon as the law governing the College of Physicians and Surgeons, shall be modified so as to allow such extension, and such modification in the length of the curriculum shall then apply to any person admitted to the study of medicine after the sanction of such law.

Any person coming from a college or university recognized by the Board, in the British Colonies or in a foreign country, who desires to obtain the license of the college, must first pass the preliminary examination before the Examiners appointed by the Provincial Medical Board, or evidence to the Board, that an equivalent examination has already been passed. He shall moreover attend in an institution of this Province, such courses as may be necessary to complete the curriculum required by the Board, and then undergo the professional examination before the Provincial Medical Board. Such examination may, however, be passed immediately after the preliminary examination.

Every candidate for a license shall furnish proof that he is twenty-one years of age.

The examination for obtaining the license shall be divided into primary and final. The primary examination shall comprise the following subjects: Descriptive and Practical Anatomy, Normal Histology, Chemistry, Physiology, and even General Pathology, Materia Medica, Hygiene, Bacteriology, and Pathological Histology, should the universities so desire.

The final examination shall comprise: General Pathology, Morbid Histology and Anatomy, Hygiene, Bacteriology, Materia Medica, Pharmacology and General Therapeutics (students may, at the discretion of the universities, undergo the examination on the above subjects, at the time of their primary examination); Medicine and Surgery, Obstetrics, Diseases of Infancy, Gynecology, Nervous and Mental Diseases, Pediatrics, Operative and Minor Surgery, Medical Jurisprudence and Toxicology, Ophthalmology, Otology, and Rhinolaryngology.

Saskatchewan.—There shall be a college of physicians and surgeons for the Provinces of Saskatchewan, called "The College," and the members of the said college shall be a body corporate under the name of "The College of Physicians and Surgeons of the Province of Saskatchewan."

Only those persons whose names are inscribed in the register and who are not under suspension by the council shall be deemed to be qualified and licensed to practise medicine, surgery, and midwifery in the province.

The council shall admit upon the register:

(1) Every person registered as a member of The College of Physicians and Surgeons of the Northwest Territories at the time of the coming into force of this Act and whose fees at such time are fully paid to the said college;

(2) Any person who shall produce a diploma of qualification from any college or school of medicine and surgery recognized by the college which exacts for such diploma attendance upon a course of lectures extending over a period of four years

and embracing at least six months of each year, evidence of which shall be produced if required, and who shall furnish to the council satisfactory evidence of identification and pass before the members thereof or examiners appointed by them for the purpose of a satisfactory examination appertaining to the profession of medicine and his fitness and capacity to practise medicine, surgery and midwifery and shall pay to the registrar of the college the sum of fifty dollars toward defraying the expenses of the examination board and in addition the fee for registration. The fee for registration is $50.

Cuba.

The graduate of a foreign school must present his diploma for registration to the medical department of the University of Havana. If this diploma is approved the candidate will be admitted to examination upon payment of a fee of $35. The applicant must undergo a theoretical examination, in which the professors constituting the board may question him, *ad libitum*, upon all matters that are subjects of study in the University course of medicine. The following day the examination will consist of two parts: The first part will consist of the clinical examination of a patient, in whose case the applicant must make a diagnosis, in the presence of the board, as well as a prognosis and plan of treatment. In the second part he must describe the method of performing an operation, selected by chance from the "*Cuestionario de Medicina Operatoria*" used in the examination for the degree of licenciate in medicine, in accordance with existing rules. The last part of the examination will take place on the following day and will consist of the writing of a thesis upon a subject selected by lot from ten proposed by the professors. For the preparation of this thesis, he will be allowed five hours, during which he must not communicate with any one, the board taking such measures as it may deem necessary to secure this end. After writing this thesis, the applicant must read it before the board, three members of which, designated by the president, will question him in regard thereto. When this last part of the examination shall have ended, the board will declare the candidate either "Admitted" or "Rejected."

The examinations, both oral and written, must be in the Spanish language, or through an interpreter. In the latter case the interpreter will be entitled to a fee of $15. The department in charge of public instruction will issue to such person as may pass this examination a degree, in the same form as that issued to graduates of the University of Havana, but stating therein that it has been obtained by examination, on presentation of a foreign diploma. The degree so issued shall have the same legal status as those issued to the graduates of the University of Havana.

Secretary of the Faculty of Medicine and Pharmacy in the University of Havana, Dr. Hernando, Havana, Cuba.

Hawaii.—The applicant must have a diploma from a reputable college whose curriculum embraces not less than four years of study; references of character, etc., and application is made to the Board of Health accompanied by a fee of $10. Then the applicant is referred to the Board of Medical Examiners, composed of three physicians, and is examined by them upon the following subjects: Obstetrics and Diseases of Women; Anatomy, Surgery and Histology; Medicine and Materia Medica; also Pathology. The examinations are written, and occasionally there is an oral examination added to it.

There is no reciprocity.

Chairman of the Board of Medical Examiners, Dr. G. Herbert, Alakea street, Honolulu, Hawaii.

Philippine Islands.

The Board issues a certificate of registration to any person who furnishes satisfactory proof of having received a diploma as Doctor of Medicine from a chartered medical school or college in good standing, or a degree as licentiate of medicine and surgery from the St. Thomas University in the city of Manila, or who has received permission to appear before a Medical Board for examination with a view of obtaining a license to practise medicine, and who passes a successful examination before the Board in Anatomy, Physiology, Chemistry, Materia Medica and Therapeutics, Pathology and Bacteriology, Hygiene, Surgery, Practice of Medicine, Obstetrics, Diseases of Women and Children, Diseases of the Nervous System, Diseases of the Eye and Ear, and Medical Jurisprudence. Examinations may be written or oral, or both.

Examinations are held on the second Tuesday of January, April, July, and October.

Examination fee, $15. In case of failure, the applicant is not permitted again to present himself for examination until the period of six months has elapsed.

Reciprocity, none.

Secretary of the Board of Medical Examiners, Dr. W. F. Dudley, St. Paul's Hospital, Manila, Philippine Islands.

Porto Rico.

Each applicant must furnish proof that he "is a graduate of a medical school or institution in good standing and legally organized, and duly approved by said board of examiners. If the diploma is found genuine, which fact the said board of examiners shall determine, and if the person presenting and claiming said diploma be the person to whom the same was originally granted, at a time and place designated by said board, or at a regular meeting of said board, said applicant shall be required to take an examination embracing those general subjects and topics, a knowledge of which is commonly and generally required of candidates for the degree of doctor of medicine by reputable medical colleges in the United States." "The standard for examination is that for the New York State regents, and a study of their reports will give an idea of the nature of the examination here" (Secretary of Superior Board of Health, February 1, 1904). "Applicants who possess diplomas from reputable medical colleges, and who have been licensed by State boards, may, upon the payment of a fee of twenty-five dollars ($25), be licensed by the board of examiners without examination if the board of examiners so decides." The fee for the examination is $10; and $5 for a certificate if issued. In case of failure to pass the examination, the applicant shall be entitled to a second examination within six months without further fee.

Examinations are held on the first Tuesday of April and October at San Juan.

Secretary of the Board of Medical Examiners, Dr. Quevedo Baez, San Juan, Porto Rico.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, April 24, 1909.

THE THRESHOLD OF PRACTICE.

To the graduate in medicine the morning after the Commencement exercises is usually a time of serious reflection. The four years of preparation for his life work are over, he has acquired more or less of a theoretical knowledge of medicine and has his diploma in proof thereof, and now the problem is how to turn this acquisition to account. He is a physician, indeed, but the title is an empty one. He is not yet prepared to treat disease and must, if in any way possible, supplement and crystallize his theoretical knowledge by practical training in the wards of a hospital before assuming the grave responsibility of ministering to the sick. But even after the hospital experience, however fit he may be to practise, the State demands that he demonstrate his fitness before she will give him the legal right to exercise his calling. Unfortunately, there is no Federal license law, and the provisions in the different States are not uniform, so one who would settle in any locality must first acquaint himself with the medical law and the conditions for examination in that particular State. After the examination has been satisfactorily passed, however, and the license secured, the beginner's troubles may not yet be over—in many cases they may be said to have only begun. It is one thing to have the ability and the right to practise medicine, and another thing entirely to get the opportunity to do so. To the man with influential friends or with means sufficient to provide for his support during the years of waiting, the outlook is not disquieting: he is either plunged at once into the active practice of his profession under the guidance of an experienced elder, or he waits with what patience he can command until a clientele is built up, employing his abundant leisure in the meantime to continue his studies and fit himself more fully for the responsibilities that are sure to come. To the young graduate without means or influence, however, the problem of subsistence becomes at once more serious.

In the present number of the MEDICAL RECORD will be found a series of articles, courteously written at the request of the editor by men of experience and practical knowledge of the topics of which they treat, designed to guide the young physician in his choice of a career and to point out the opportunities there are of making a living outside of regular practice. These may be roughly divided into three classes—those which offer a permanent career outside of civil practice, such as the public services; those which offer only a temporary assistance, such as most of the municipal appointments; and those which offer a more or less permanent supplement to the income from private practice, such as appointments as insurance examiners, railway surgeons, surgeons to the police and fire departments in the larger cities, etc.

It will surprise some of our readers, no doubt, to learn how many ways there are of increasing one's income in a method not inconsistent with professional dignity, and we hope many will be helped by the information here given to bridge over the critical period of beginning professional life. A word of caution is, however, necessary. The man who wants to succeed in general practice must look on these various helps as merely temporary makeshifts, and form the resolution, and adhere to it, to give them up as soon as his practice will support him. If, seduced by the security which a salary, however small, gives him, he follows the extra-professional, or rather extra-practical, calling too long, he will in the end become dependent upon it, and the demands it makes upon his time and strength will seriously handicap him in the race for success in practice.

It is different, of course, with the public services and some other positions which carry with them a living salary from the beginning. These offer the young physician a career outside of private practice, and should be taken up only as a life work. The man who enters the Army, the Navy, or the Public Health and Marine-Hospital Service with the idea of remaining there only a few years and then resigning to enter upon private practice, makes a fatal mistake. The training he receives in these services is not well adapted to fit him for civil practice, and his salary in the early years is hardly more than enough for daily needs, so that it will be practically impossible to save a sum sufficient for support during the waiting period.

But there are other things of interest to the medical graduate besides the choice of a career and the question of immediate support. These weighty matters being settled, he has still to remember that he has been admitted to a learned profession, one in which the sum of knowledge is immense and is increasing with amazing rapidity. If he would keep up with his fellows his life must be one of constant and unremitting study. If he neglects this it will not be for lack of opportunity. The output of medical books, new books and new editions, is very large; in every issue of the MEDICAL RECORD there is a page, and sometimes two, containing notes or more extended reviews of six or eight medical books—in the year 1908 no less than 339 books were reviewed. Any one reading this page each week, or the list of new books which is published from time to time, can keep himself well informed regarding the permanent literature of his profession. But, important as it is to collect a good working library of books of reference, it is even more important for a physician worthy of the

name, who accounts himself a member of a learned profession and who would give himself and his patients the benefit of all that is newest and best in his science and art, to keep abreast of the rapid progress therein by reading the medical journals. There are many excellent medical journals in this country from which the young physician can make his choice. If he can take but one journal it should be one of the larger weeklies, but he will do well, if he can, to read also one of the important monthly periodicals and to subscribe to his local journal which will keep him informed of what is going on in his own neighborhood. To these he may add, if he inclines to some particular branch of medicine, one of the journals devoted to a single specialty.

The young practitioner, whose means will permit and who can afford the time, will find much profit in a visit to the teaching centers of Europe, where he will learn not so much new things as new or unfamiliar ways of doing the old things. They may be better ways than those he has learned at home, or they may be not so good, but it will profit him to observe them, it will broaden his outlook and give him a better understanding of how to apply the knowledge he already possesses. Many practical hints to one contemplating such a tour of observation and study will be found in the article in this issue on Post-Graduate Study in Europe. We have not included an account of the post-graduate schools in this country, for they are not so much for the use of the recent graduate as for one who has been practising for some years away from the medical centers and feels the need of brushing up his knowledge and familiarizing himself with the most recent methods of diagnosis and treatment. For one who contemplates devoting himself more exclusively to some particular branch, or even becoming a pure specialist, a course in a post-graduate school and a term of service in a special clinic or hospital will be indispensable. But this also is for a later period. The would-be specialist should never think of becoming one until he has had several years of general practice; he will be a narrow man if he does and will be a failure as a specialist. When the time comes, however, that one's general medical knowledge and experience are sufficient to fit him to become a specialist in any one branch, he need not go abroad to prepare himself for the task. The post-graduate schools in any one of a dozen of the large cities in this country will give him all that he needs in the way of clinical material and of thorough training in diagnostic and therapeutic methods.

The physician is, like men in every other calling, a member of the body politic; he has rights as a medical practitioner which other members of the community are bound to respect and he has duties to his fellow-citizens and his patients which he is under obligation to fulfil. Every citizen is supposed to know what the law demands of him in his relations with his fellows, but there are in addition certain legal rights and obligations peculiar to the physician which should be thoroughly understood by the young practitioner who would avoid the annoyance and expense of a possible malpractice suit, or the chagrin of being unable to establish his claim for professional services rendered those able but unwilling to pay. All that is necessary for him to know in this regard may be learned from the very practical article on the Legal Rights and Obligations of the Medical Practitioner in this issue.

Finally, if we may be permitted a word of advice and of warning to our new colleagues in this, which we are wont to call, with seeming conceit but really some truth, the noblest of professions, we would say that upon you depends whether it shall be such or not. The practice of medicine is a means of livelihood, but also a charitable profession. The physician's duty is to prevent disease, without a fee, as much as it is to cure disease, with or without a fee, as the case may be. He must be a public man, a man of prominence in his community, as well as the confidant of his patients and the alleviator of suffering. If an epidemic of disease breaks out in his community, he must search for its cause and proclaim the cause, when it is found, no matter what interests he may antagonize in so doing. Then he must be ever ready to respond to the call of suffering, even if this call comes from one whom he has relieved before and who has failed to recompense him. On the other hand, he must insist upon his just dues; his bills for service should be rendered promptly, and if they are not paid and he is sure that the non-payment is not because of pecuniary inability, he must not hesitate to invoke the law if necessary. In all this nice adjustment between his duty to the public, to the suffering, and to himself and his family, there will be a call for infinite tact, and tact—not chicanery—is the secret of success in medical practice. One must be all things to all men, but honest and honorable withal.

THE MEDICAL SCHOOL AND THE STUDENT.

The well-considered addresses delivered at the recent meeting of the Association of American Medical Colleges in this city emphasized what most of us have been cognizant of for some time, namely, that whatever merits the present methods of instruction may have in comparison with those used twenty years ago, there is still much to be desired in the matter of adjusting the curriculum to the student's needs. To be sure a great stride has been taken in equalizing the requirements for preliminary education so that young men taking up the study of medicine shall be equipped equally to a certain extent, and hence shall have the foundations for future acquisition of knowledge laid deep and wide. So far so good. There is, however, no good reason why the medical school should undertake to teach its students such fundamentals as general chemistry, physics, and biology. These subjects do not belong in the purely medical curriculum. They belong to the advanced high school and university courses, which are, as a rule, better able to supply the essentials of material and competent instructors than the unaffiliated medical school can ever hope to be.

If our students are not educated up to the standards that obtain in the Old World, and the implied

consensus of opinion of the speakers at this meeting seemed to be that they are not, is it not because we are crowding into a few short months facts and theories which cannot be rapidly assimilated? The continental term of study is five, six, or seven years. How can America teach in four years what can scarcely be taught elsewhere in six or seven? Counting out the Christmas and Spring vacations, and single holidays, the school year consists of only about seven and one-half months; hence at graduation a student has had about thirty months of actual instruction. As a result, any one lesson assigned must consist of many pages of a textbook to be practically memorized, besides such notes as the instructor may have dictated or given in lecture form from time to time. This means for the average student three solid hours of preparation; and if he is unfortunate enough to have two or more such recitations falling on the same day he comes into the classroom his head crammed with a mass of undigested facts, his memory rebelling under the strain, and his attention distracted by its burden of over-application.

To be of excellence and practical usefulness the course should be especially strong on diagnosis and treatment, particularly treatment by other means than surgery. The only place one can really acquire a working knowledge of surgery is during an interneship in the wards and operating rooms of a large general hospital. If it could be so arranged it is during such incumbency that lectures in surgery would be of the most value, when the subject matter is fresh and illustrative material close at hand. Special subjects, such as diseases of the eye or of the nose, throat, and ear, should be taught almost exclusively from the standpoint of diagnosis. No hard-worked general practitioner can do justice to the treatment of these diseases; all that he can do in most cases is to make a diagnosis of the actual condition present in order to refer the patient to a physician who makes these things his special study. If the future practitioner's work is to be in the country he must prepare himself in the special branches by post-graduate study.

Instruction in therapeutics is in too many schools inadequate and incomplete. Few students when they are graduated know how to write out a diet for hyperchlorhydria or intestinal putrefaction, or how to use hydrotherapy, or electricity, or massage, including the so-called osteopathic movements. Patients are going to demand these things, and consequently are going to drift away from their medical advisers, who ought to know how to administer such treatment, to others who may know how, but do not know when or how much. Even the materia medica is often slurred over, or the student's time is wasted in learning how to recognize the crude drug, as though he was to gather his own simples, or how to extract the active principles or make the tinctures or fluid extracts, as though he was to be his own manufacturing chemist. The curriculum of the medical school is too crowded. The term of study should be lengthened or only the essentials should be taught, and taught practically, in the four short years of the medical course.

MEDICAL PARTNERSHIPS.

A Massachusetts court was recently called upon to decide upon the validity of a partnership contract between two physicians. A young man was engaged as the assistant of an established practitioner upon the understanding that he should receive one-half of the money collected for work done by himself, and further that he should not practise independently in the same town during the lifetime of the older physician in case the partnership was dissolved for any cause. Under the terms of the covenant either party could terminate the agreement on giving ten days' notice to the other party. After the partnership had existed two or three years, one of the associates, which one it does not appear, terminated the agreement and the younger man opened an office in the same town and set up for himself. Thereupon the older man brought suit to restrain his quondam partner from practising there, and the court decided in his favor. The decision seems to have been a just one, but the case illustrates one of the disadvantages of a medical partnership. If the younger man had given honest service and had been discharged because the senior partner found he was becoming too popular with their patients, it was hard for him to lose everything but the half fees he had earned and be forced to start anew in another town among strangers. On the other hand, if he had been engaged in undermining his partner's hold on the patients, who were originally the older man's, and when he felt himself strong enough in their confidence had suddenly terminated the agreement in order to rob his former partner of a part of his clientèle, it was manifestly unfair and he deserved his sentence of banishment.

A partnership between two men of honor is often mutually advantageous. The senior member, having a large practice which taxes his possibly failing strength, and in any case of the burden of which he wishes to be in a manner relieved, gladly avails himself of the assistance of a young and active man, fresh from the school and the hospital and skilled in all the newer laboratory methods. He turns over to the junior partner the care of the minor cases and the work of watching by the bedside in the serious cases, securing thereby for himself more sleep and a clearer mind for the solution of the difficult problems of practice; and the younger man can also make the urinary and blood examinations which may be necessary. The junior partner enjoys the advantages of immediate occupation, of an introduction to a large clientèle which he otherwise would have had to wait and work many years to obtain, and, last but by no means least, he will have the opportunity to profit by the wisdom of the older practitioner and to supplement his theoretical training by practical instruction at the bedside under the guidance of a man of wide experience and mature judgment.

In any partnership there are, of course, some disagreeable features; the patients naturally prefer the older man and some of them will resent being committed to the ministrations of the junior and may not hesitate to make their displeasure manifest. But with tact and conscientious attention to duty, the

young man will gradually win the confidence of the patients, and, even without any conscious effort on his part, they may come to prefer him to his partner. This is the disagreeable feature for the senior, but it is only what he must expect, and if he is a man with a saving sense of humor he will regard the situation with equanimity and without jealousy. When, in the course of time, the partnership is amicably terminated, the younger man will find himself with an established practice and with a true friend as a colleague to whom he can turn for advice or whom he can call in formal consultation; the older man, still with a clientèle of devoted patients sufficient in number to keep him as busy as he wishes to be, is content in the knowledge that he has a grateful friend in the profession to whom he can turn for assistance in time of disability or when he takes a needed vacation. This is the ideal medical partnership, the successor of the former institution of instructor and student in the olden times when colleges were few and the neophyte received his entire training, theoretical and practical, in the office of the family physician. Such human partnerships still exist, and that there are others marred by wrangling and mutual jealousies is no more an argument against medical cooperation than are the annals of the divorce courts on argument against marriage.

THE ATTITUDE OF THE PUBLIC TOWARD POST MORTEM EXAMINATIONS.

"Experience is fallacious and judgment difficult." This is the saying of Hippocrates which Osler has chosen as the epigraph for his book on the "Practice of Medicine," and in spite of the many centuries which have passed since those words were first pronounced, the truth of them, so far as medical experience and judgment are concerned, remains as absolute as it was then. Medical art and science are both very imperfect branches of human activity and knowledge, the immense addition to them obtained by the researches of the last few decades simply serving to accentuate the facts concerning the human organism which are hidden from us at present and promise to remain thus for a long time to come. The progress of the last few decades can be traced in the main to the introduction of one important method of study, that of animal experimentation in the laboratory. The thoughtless agitation carried on by the antivivisectionists in favor of restrictions upon animal experimentation seems almost criminal when the amount of knowledge gained by such experimentation and the results of the application of such knowledge to human therapy are considered. Animal experimentation has become so valuable an asset in the study of pathological conditions because it has brought with it the possibility of studying diseases of function and the observation of disorders intelligently and purposefully produced in the living animal and so aiding in the study of disease as it occurs in the human or other organism independent of any wilful and purposeful interference. Just as careful dissection of the human body soon served to overthrow the imaginary ideas of its structure founded upon preconceived notions, so the introduction of animal experimentation has dispelled many idle and unfounded explanations of the phenomena of health and disease derived from observation uncontrolled by experiment.

There has, however, always existed another method of adding to the store of medical knowledge, a method which is even more productive of immediate results than animal experimentation, and that is the careful examination of the bodies of persons dying of disease. A carefully performed autopsy gives the best possible explanation for the clinical phenomena observed during the life of the patient, points out the limitations of the means of observation at our command and, in general, serves to facilitate correct diagnoses in similar or other conditions, occurring in the future practice of the physician witnessing the autopsy. There is no need to accentuate at this late date that correct diagnosis leads to correct treatment, and the introduction of new therapeutic methods founded upon the results of animal experimentation has made it possible to have such treatment effectual in curing disease in a much greater proportion of cases than heretofore.

These facts have long been recognized in Germany among both medical men and the lay public, and the autopsies performed in that country probably exceed in number those of any other land; there is no doubt, too, that the great advances in medical art and science which we owe to German physicians are largely due to their greater opportunities of acquaintance with the anatomical changes produced by disease. The trouble in our land does not lie directly with the medical profession, but is due to the lack of an intelligent public opinion on the question. Our newspapers very frequently print notices of this or that man who has "willed his body to science" as if such bequest was of any great value so far as progress of medical knowledge is concerned. It cannot be said that our colleges lack dissection material, yet this is about the only use to which a body of one whose disease has not been carefully watched can be put. On the other hand, the great majority of the bodies of patients dying in the hospitals of this city, for instance, are interred without any post-mortem examination, just because the public has not yet been taught to understand the great importance of such examinations for the training of the men who take care of the health of the public, as well as for the progress of medical knowledge in general.

The medical press must lead in the proper education of the public in this respect and it is to be hoped that agitation in medical publications will call forth expressions of opinion from writers in the general press favoring the granting of autopsies in cases where the attending physicians consider it profitable and important to have them. There are already institutions in America that reserve the right of having the bodies of persons dying while under their care examined after death and the introduction of such a provision among other hospitals may be quickly realized if public opinion is properly educated. This matter is certainly as important as any of the questions which the American Medical Association has decided to bring before the laity,

and it may be hoped that some measures will be taken at the next meeting of the Association to have the point of view held by the profession explained to the general public. In the meanwhile it should be almost a matter of routine in our hospitals to insist upon post-mortem examination of persons who have died of some obscure disease which only such examination could clear up, or in cases of more usual pathological conditions which have run an unusual course and have not responded properly to treatment. There is no doubt that such examinations will greatly enhance the training value of a hospital course for the internes and make of them better practitioners of medicine as well as stimulate those who are naturally fit for scientific research to give up time and labor to this field of medical activity. The public must be taught to understand the fact that the granting of an autopsy is not a favor to the physician asking for it, but a mere legal acquiescence in what is his moral privilege to demand because of the care and time he has bestowed upon the patient. Mere curiosity is not the feeling that leads to such request on the part of the busy cosmopolitan physician; it is the desire to improve his knowledge of medicine so that the next man may have a better chance of being delivered from his affliction, a desire in the realization of which all right-thinking people ought to assist as far as it is possible for them to do so.

Medicine of the Future.

It is a curious fact and one that is often commented upon that the greatest efforts of the medical profession, the members of which are dependent for their living upon the treatment of disease, are directed toward reducing the number of the sick; the profession of medicine, so far as it is a profession of healers, is constantly and strenuously engaged in digging its own grave. In concluding a chatty and interesting little book,* one that is filled with practical therapeutic hints and random notes on all sorts of medical topics, W. J. Tyson, noting this strange phenomena, attempts a forecast of what the result will be of this trend of medical healing and practice. The teaching of hygiene and preventive medicine will, he thinks, increase more and more and become part of the regular curriculum of the primary schools. When, as a result of this, a knowledge of the general principles of physiology and of the laws of health is the common property of all men and women, "medicine will no longer be looked upon as the art of curing disease, but as a science of preventing such of them as cannot be altogether abolished." As a direct consequence of this, he believes, if men are going to gain a livelihood by practising the medical profession, fewer men must be admitted to its ranks, and these highly qualified; moreover many of these will be supported by the State in return for the work they do in preventing the causes of disease. Doubtless he is right in believing that many diseases will be largely prevented, if not entirely abolished, these being in great part the infectious diseases; but there will still remain a multitude of ills, diseases of the vascular, nervous, and digestive systems, brought about by individual habits and modes of living which will never be wholly corrected so long as civilization remains what it is. Physicians are themselves among the greatest sufferers from these ills, and if they, the teachers of hygiene and preventive medicine, do not escape, there is little hope that others will be more fortunate. Sickness and death will never be abolished; some diseases may become extinct, but others will take their place and mankind must pass yet through many centuries of evolution before the profession of healing will be of the past.

*Notes and Thoughts from Practice, by W. J. Tyson, M.D., F.R.C.P., F.R.C.S. John Bale, Sons & Danielsson, London, 1909.

News of the Week.

An Examination for Medical Interne, Government Hospital for the Insane.—The United States Civil Service Commission announces an examination on June 16, 1909, at the places mentioned in the list to be found elsewhere in this issue to secure eligibles from which to make certification to fill at least two vacancies in the position of medical interne (male), Government Hospital for the Insane, Washington, D. C., at $600 per annum each, with maintenance, and vacancies requiring similar qualifications as they may occur in that hospital. From the grade of medical interne the hospital makes promotions to the next higher position in the medical staff as vacancies occur. As considerable difficulty has been experienced in filling vacancies in the position of medical interne in the hospital service during the past several years owing to the limited number of eligibles available, qualified persons are urged to enter this examination. Applications will be accepted only from persons who have been graduated from reputable medical colleges not more than two years prior to the date of the examination. Both men and women will be admitted to this examination. Applicants must be unmarried. Age limit, 20 years or over on the date of the examination. Applicants should at once apply either to the United States Civil Service Commission, Washington, D. C., or to the secretary of the board of examiners at any place in the list above mentioned for application form 1312. No application will be accepted unless properly executed and filed with the Commission at Washington.

Council on Medical Education.—The fifth annual conference of the Council on Medical Education of the American Medical Association was held at the Auditorium Hotel, Chicago, April 5, with the Chairman, Dr. Arthur Dean Bevan, presiding. Reports were presented by the chairmen of the ten sub-committees on medical curriculum. The reports recommended a curriculum which aggregated 4,400 hours. On the day preceding the conference a comparison of these reports was made, duplicates of courses eliminated, and the total hours for each section reduced as follows:

Subject.	*Hours.*
1. Anatomy, including histology and embryology	700
2. Physiology and physiological chemistry, including 80 hours of organic chemistry	530
3. Pathology and bacteriology	500
4. Pharmacology, toxicology, and therapeutics	240
5. Medicine, including pediatrics and nervous diseases	800
6. Surgery, general and special	650
7. Obstetrics, 180 hours, and gynecology, 60 hours	240

8. Diseases of the eye, ear, nose, and throat..	140
9. Dermatology and syphilis.....	90
10. Hygiene, medical economics, and medical jurisprudence	120
Total	4,010

These figures represent the maximum requirement of a medical curriculum covering four years of thirty two weeks each of actual work.

University of Pennsylvania Home-coming.—The week of April 12 was devoted by the Medical Department of the University of Pennsylvania to a series of meetings and demonstrations illustrative of the progress being made in the field of medical activity. The exercises were opened on April 12 by a gathering at the Henry Phipps Institute for the Study, Prevention and Treatment of Tuberculosis, where a number of addresses were made on the subject of tuberculosis. On April 13 clinics were held by various members of the Medical Faculty and teaching corps, and in the evening Army and Navy Night was celebrated by a smoker given by the Philadelphia Alumni of the Medical Department in honor of members of the medical corps of the Army and Navy. On the evening of April 14 a dinner was held, and addresses were made by Provost Harrison, U. S. Attorney-General Wickersham, Dr. James Tyson, Dr. A. E. Taylor, and Dr. S. Weir Mitchell. On April 15 the new clinical laboratories were formally dedicated. On April 16 an address was delivered by Dr. A. E. Taylor on "The Relation of the Stomach and the Intestines to the Work of Digestion," and later a reception was held in honor of Dr. Taylor and other visiting alumni.

Philadelphia Medical Club.—A reception was held on April 16 in honor of Dr. Joseph S. Neff, Director of Public Health and Charities of the City of Philadelphia. In an address Dr. Neff spoke of the importance of educating the public in hygienic and sanitary matters. He pointed out the advances made by preventive medicine and the promise for the future from this source. He emphasized the necessity of diminishing infant mortality, and he dwelt upon the necessity of securing accurate vital statistics. He appealed for the coöperation of physicians in the maintenance of accurate statistical data in his department, in the strict preservation of quarantine, and, in particular, in rooting out malpractitioners.

The New York Milk Committee.—This committee, which is a part of the Association for Improving the Condition of the Poor, met at the Bar Association on April 11, to consider means to insure the production and distribution of pure milk throughout the State and city. Mr. Stephen G. Williams is the president of the committee, and Mr. W. C. Phillips is secretary. It was decided to ask for the organization of a State milk committee to safeguard the quality of the milk, this committee to be composed of city milk dealers, up-State farmers and dairymen, consumers, lawyers, physicians, and social workers. It was also decided to continue the committee's present milk depots, and to publish frequent bulletins on matters pertaining to milk. The Committee on Laws and Legislation of the Board of Aldermen is considering an ordinance providing that no milk or cream shall be sold at retail in the city unless it comes from herds certified to be free from tuberculosis. Milk and cream must also be certified by the Department of Health as not containing more than 500,000 bacteria to the cubic centimeter, all milk or cream which is not thus certified to be pasteurized under the supervision of the Health Department.

"The Military Surgeon" Changes Editors.—With the April issue of the *Military Surgeon*, the monthly journal of the Association of Military Surgeons of the United States, Dr. James Evelyn Pilcher relinquishes the editorial chair which he has for many years so adequately filled. His retirement will be a loss to the *Military Surgeon* and to medical journalism at large. He will be succeeded in the offices of secretary and editor by Major Charles Lynch, U. S. A. All communications to the Association or to the *Military Surgeon* should be addressed to Major Lynch at Washington, D. C.

Visiting Nurses.—The Department of Health of New York has again taken up the work of saving the lives of the city's babies by means of the instruction of mothers by a corps of visiting nurses. One hundred and forty-one nurses began the work on April 16, under the supervision of Dr. S. Josephine Baker. The visiting and instruction will be carried on along the lines which proved so successful last summer, and as the work has been begun two months earlier this year than last, it is hoped that better results will be obtained.

The Quarantine Commission.—A new bill to abolish the office of Quarantine Commissioners of New York, and to turn the work entirely into the hands of Dr. Alvah H. Doty, Health Officer of the Port, has been introduced into the State Senate. At present all but one of the Quarantine Commissioners are out of office, either through death or other cause. This legislation has been recommended by the Governor for two years past.

Conviction for Selling Cocaine.—A druggist of Grand street, New York, was found guilty in the Court of General Sessions of selling cocaine, and was sentenced on April 13 to eleven months and twenty-nine days in the penitentiary, and to pay a fine of $500.

Street Car Accidents.—During March, 1909, twenty persons were killed on the railroads of New York City, and 2,434 were injured. The figures for March, 1908, as given in the report of the Public Service Commission, were forty-four killed and 2,631 injured.

State Reservation at Saratoga Springs.—The Senate, on April 13, passed the Bracket bill providing for the appointment of a commission to purchase the springs at Saratoga for a State reservation. The bill carries an appropriation of $600,000 for the purpose.

Dr. Lucy Waite has resigned her position as head surgeon in the Mary Thompson Hospital of Chicago for Women and Children and has retired from practice.

Dr. Julius Grinker of Chicago was recently appointed a member of the consulting staff of the Cook County Hospital.

Municipal Tuberculosis Sanatorium of Chicago.—Drs. William A. Evans and Theodore B. Sachs have been appointed Directors of this proposed institution.

New Hospital Heads.—Governor Hughes of New York has sent to the Senate the following nominations of managers of State institutions: Dr. Whitman V. White, New York, Manhattan State

Hospital; Dr. Maximilian Toch, New York, Central Islip State Hospital; Dr. John T. Rafferty, Brooklyn, Kings County State Hospital.

The New York State Branch of the Red Cross held a conference in New York from April 13 to 16. Mrs. W. K. Draper, the secretary of the branch, announced that in New York City alone more than $15,000 had been raised by the sale of the Christmas stamps, all of which is being used in the fight against tuberculosis. A strong appeal was made for more nurses to take up the Red Cross work.

Rockefeller Institute Hospital.—Miss Nancy P. Ellicott, a graduate of the Johns Hopkins Training School for Nurses, and formerly superintendent of the Church Home and Infirmary of Baltimore, has been appointed to a similar position in the new hospital of the Rockefeller Institute. The appointment of Dr. Rufus I. Cole, associate in medicine in the Johns Hopkins Medical School, as medical director of the hospital has already been announced.

Hospital Changes Name.—The Mercy Hospital is the new name given to the old City Hospital of Baltimore, Md., which has been for many years skillfully and successfully managed by the Sisters of Mercy. The old name was misleading as implying that the institution was a municipal one, which is not the case, out of the 250 beds only about ninety being maintained by the city as free beds for public dependents. The hospital is shortly to be enlarged at a cost of about $300,000, and will then have accommodations for some 550 patients. It is also rumored that the College of Physicians and Surgeons of Baltimore, which is connected with the Mercy Hospital is to be enlarged by a very substantial addition, affording both laboratory and clinical rooms, the lack of which has long been felt.

Vacancy at Gouverneur Hospital.—It is announced that a vacancy exists at present in the position of Attending Physician to Out-Patients at Gouverneur Hospital, with which is associated the position of Assistant Attending Physician to the Hospital proper. Applications for appointment to this position may be addressed to Dr. John H. Huddleston, secretary of the Medical Board of Gouverneur Hospital, Gouverneur and Front Streets, New York.

City Hospital Staff House.—Janeway Hall, the recently completed home for the staff of the City Hospital on Blackwell's Island, New York, was opened on April 15, with appropriate ceremonies. Among the speakers were Commissioner Hebbard, Archdeacon Nelson, Dr. John A. Fordyce, President of the Medical Board of the Hospital, and Dr. William Rhinelander Stewart. The new building has been fittingly named for Dr. Edward G. Janeway, whose connection with the hospital dates back many years. To the right of the main entrance of the house has been set a bronze tablet bearing an inscription setting forth the distinguished service rendered by Dr. Janeway. The house will accommodate twenty-five physicians, is four stories high, and has cost about $75,000. Its opening will make it possible to increase the capacity of the City Hospital by about one hundred beds, through the releasing for ward purposes of space formerly needed for housing the staff.

Illinois Psychopathic Hospital.—On April 16, the Public Charity Service of Illinois opened its fourth new psychopathic hospital at Anna, when the new hospital building, built in connection with the Illinois Southern Hospital for the Insane, was formally dedicated. The appropriation of $25,000 for a similar institution at Elgin was insufficient, and an additional appropriation of $15,000 is asked of the present General Assembly to complete a modern fireproof psychopathic hospital at Elgin.

Colonies for Epileptics.—The Illinois State Board of Charities proposes three colonies for epileptics if the Legislature will grant the necessary appropriations. The proposition for Illinois is to attempt to provide for all epileptics in the State, those in asylums for the insane and feeble-minded, those in county almshouses, and those who are cared for in private homes. It is hoped and thought that the Legislature will take favorable action and grant the request of the Board in this important matter.

Caroline Rest.—The new home for needy mothers and children at Hartsdale, N. Y., to be known as Caroline Rest, will be opened on May 5. The home, which has been built as a memorial to Mrs. Caroline Schrader, will be under the management and control of the New York Association for Improving the Condition of the Poor. It is intended to be, not only a sanatorium for sick mothers and infants, but a school where, under most favorable conditions, mothers will receive instruction in the duties of motherhood, personal hygiene, care of children, and conduct of homes.

Gifts to Charities.—The Hospital for the Ruptured and Crippled, of New York, will receive one-third of the estate of the late Miss Jane Pindell, who died recently.

The Children's Free Hospital of Cedar Rapids, Ia., has received a gift of $4,000 from Mr. Daniel W. Norris to be used in erecting a detention ward and gymnasium.

Announcement has been made that Mrs. G. F. W. Duff, of New York, will build and equip a children's hospital in Augusta, Ga., as a memorial to her husband.

By the will of the late Charles E. Ellis, of Philadelphia, a sum believed to be in the neighborhood of $3,000,000 is devised as an endowment fund for a college for the education of fatherless white girls. Work upon a building is to be begun as soon as the sum of $100,000 shall have accrued in interest. In addition, the sum of $10,000 is bequeathed to the Presbyterian Hospital for the endowment of a private room. Also the sum of $500 annually in two equal payments is bequeathed to the Sanitarium for children at Red Bank.

By the will of the late Frank W. Hoyt, of Cheltenham Township, Pa., his executors are directed to endow a bed in the Samaritan Hospital, Philadelphia, to be known as the Mary Edith Hoyt Bed. Contingent bequests are made also as follows: Samaritan Hospital, Philadelphia, $10,000; Children's Hospital, Philadelphia, $5,000; Homeopathic Hospital, Philadelphia, $5,000; Free Hospital for Poor Consumptives, Philadelphia, $5,000.

Death of a Centenarian.—Mrs. Elizabeth Hunt of Brooklyn, N. Y., who would have been 100 years old on August 31 next, died on April 13. Mrs. Hunt remembered shaking hands with Gen. Lafayette when he made his famous visit to the United States.

Rabies Quarantine Extended.—The quarantine against rabies which is now in force in many cities and towns in New York State, has been extended to Binghamton, to last for sixty days from April 19.

American Gastroenterological Association.—The twelfth annual meeting of this association will be held at the Hotel Windsor, Atlantic City, N. J., on June 7 and 8, 1909. The preliminary program contains the following papers, among others: "Development of Gastroenterology in America," by Dr. J. Friedenwald, of Baltimore; "Duodenal Ulcers," by Dr. Max Einhorn, of New York; "Disturbances of the Chemic co-ordinations of the Organism," by Dr. J. C. Hemmeter, of Baltimore; "Pathogenesis of Gastric Tetany," by Dr. W. G. MacCallum, of Baltimore. There will also be a symposium on the subject of gastroenterostomy.

National Association of the Study and Prevention of Tuberculosis.—The fifth annual meeting will be held at the New Willard Hotel, Washington, on May 13 to 15, 1909. The congress will open with a general meeting on Thursday, May 13, when the vice-president, Mr. Homer Folks, of New York, will speak. Following this there will be meetings of the various sections. Among the other speakers will be Dr. Victor C. Vaughan, of Ann Arbor, whose subject will be "Tuberculosis Legislation, State and Municipal"; Dr. William H. Welch, of Baltimore, "The Selection of a Library for the Study of Tuberculosis"; Dr. G. B. Webb, "Some Hematological Studies in Tuberculosis"; Dr. John W. Brannan, of New York, "Treatment of Surgical Tuberculosis." There will be also a discussion on various methods of increasing the efficiency of the sanatorium, the subject being taken up by a number of speakers from different points of view.

Twelfth International Congress on Alcoholism.—This congress will meet in London, England, July 18 to 24, 1909. This will be the second great international congress under Government auspices to discuss the alcoholic problem, the congress two years ago having met under the auspices of the Swedish Government. The Duke of Connaught will preside at the coming meetings as Honorary President, and invitations have been sent to all the governments of Europe and America to send formally delegates. In response to this invitation the United States has appointed Dr. Thomas D. Crothers, of Hartford, Conn., as its delegate, and he has been made an Honorary Vice-president. Further information may be obtained from him.

Medical Library Association.—The twelfth annual meeting of the Medical Library Association will be held in Washington and Baltimore during the week of the meeting of the Association of American Physicians. The first session will be held at the library of the Surgeon General's office, on the afternoon of May 12, and on May 13 the members will go to Baltimore for the dedication of the new library building of the Medical and Chirurgical Faculty of Maryland, when Dr. William Osler, of Oxford University, will deliver the oration. Prof. George Dock, of Tulane University, is the president of the Association.

The Hillsborough County (N. H.) Medical Society, at its fourth annual meeting in Nashua, on April 6, elected the following officers: Dr. Eugene Wason, Milford, *President;* Dr. J. H. Gleason, Manchester, *Vice-President;* Dr. Ella Blaylock Atherton, Nashua, *Secretary and Treasurer;* Dr. J. B. Pettingill, Amherst, *Auditor;* Dr. F. E. Kittredge, Nashua, *Delegate* for three years to State Society; Dr. W. E. Reed, Nashua, Dr. J. W. Finnerty, Milford, and Dr. G. H. Greeley, Merrimack, *Executive Committee.*

The Hartford County (Conn.) Medical Association held its one hundred and seventeenth annual meeting in Hartford on April 6. Officers for the ensuing year were elected as follows: *President,* Charles D. Alton, Hartford; *Vice-President,* H. Strosser, New Britain; *Secretary-Treasurer,* Frederick B. Willard, Hartford; *Councilor,* O. C. Smith, Hartford; *Censor* for three years; E. R. Lampson, Hartford; *Delegates,* F. B. Willard, Hartford; Harry B. Rising, Glastonbury; W. R. Tinker, South Manchester; E. P. Swasey, New Britain; P. H. Ingalls, Hartford; M. H. Gill, Hartford, and J. H. Rose, Hartford.

The Middlesex County (Conn.) Medical Society, at its annual meeting, on April 8, elected the following officers: *President,* Dr. M. D. Murphy, of Middletown; *Vice-President,* Dr. M. W. Plumstead, of East Haddam; *Censors,* Drs. J. M. Keniston and J. H. Kingman, of Middletown; *County Reporter,* Dr. James Murphy, of Middletown; *State Councilor,* Dr. J. M. Keniston, of Middletown; *Delegates* to the State convention, Dr. C. E. Stanley and Dr. C. B. Young, of Middletown.

Obituary Notes.—Dr. Letchworth Smith of Louisville, Ky., died at his home, of organic heart disease, after a short illness, on April 7, aged 39 years. Dr. Smith was graduated from the College of Physicians and Surgeons of New York in 1898, and served in Porto Rico during the Spanish War. He had for some time been director of laboratories at the University of Louisville, and was chief inspector of milk in the Louisville Health department, and a member of the Tenement House Commission and the Babies' Milk Commission.

Medical Inspector Henry Tucker Percy, U. S. N., died at the Naval Medical School Hospital in Washington on March 31, from uremia, aged 59 years. Dr. Percy was graduated from the medical department of the University of Virginia in 1872, and entered the naval service during the next year. During the Spanish War he was attached to the Charleston, and later was on duty at the Norfolk and Washington Navy Yards. During 1905-06 he was in command of the United States Naval Hospital at Yokahama, Japan.

Dr. Gustav Hessert, of Chicago, Ill., died at his home on April 4, aged 64 years. Dr. Hessert was born in Germany and was graduated in 1858 from the University of Würzburg. In 1863 he settled in Chicago where he practised until his death.

Dr. Louis Benjamin Durocher, of Montreal, Canada, died at his home on April 5, aged 79 years. Dr. Durocher received his degree from the Victoria University of Cobourg in 1853, and had practised in Montreal for over thirty years. He was for many years Dean of the Laval Medical Faculty, an office which he held until 1892.

Dr. Samuel Cager Johnson, of Fitchville, Conn., died at his home on April 6. He was graduated from the medical department of the University of New York in 1877.

Dr. Albert W. Neufield, of New York, died at the Mt. Sinai Hospital on April 11. Dr. Neufield was a graduate of the College of Pharmacy and of the College of Physicians and Surgeons, New York, in 1882. He was a Fellow of the New York Academy of Medicine and a member of the New York County Medical Society and of the Harlem Medical Society, and was for many years chief pharmacist of the New York Dispensary.

Dr. George E. Tytler, of New York, died on

April 15, after a short illness, aged 60 years. Dr. Tytler was graduated from the New York Homeopathic Medical College in 1873, and was a member of the American Institute of Homeopathy, the State Homeopathic Society, and the Academy of Pathological Science.

Dr. Oscar M. Barber, for forty years a leading physician of Mystic, Conn., died at his home on April 4, aged 71 years. Dr. Barber was graduated from the New York Homeopathic Medical College in 1869. He was for several years health officer of the town of Stonington, Conn.

Dr. Henry K. Macomber of Pasadena, Cal., died at his home on March 23, of acute gastritis, aged 65 years. Dr. Macomber was a veteran of the Civil War, and a graduate of the medical department of New York University, Class of 1867.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE ROYAL COMMISSION'S REPORT ON MEDICAL POOR LAW RELIEF—TUMOR-LIKE FORMATIONS OF FAT—THE SUCKING CUSHION—CANCER OF THE STOMACH—OBITUARY.

London, April 2, 1909.

The report to the Royal Commission on the Poor Laws respecting medical relief was intrusted to Dr. C. McVail, who was instructed to inquire into the present system of both in and outdoor medical relief. He carried out his investigations in both rural and urban districts, and his report was presented on Wednesday and was in circulation yesterday. It deals with the questions involved in various aspects and makes recommendations for new administration which many will think revolutionary. In that, however, it resembles the reports of the Royal Commission, which engaged his services, for both their majority and minority reports advise changes so extensive that Sir C. Dilke, who is an experienced parliamentarian, declared the other day at the Royal Economic Society they were dead before being born, as far as practical action was concerned. It is possible Dr. McVail's conclusions may prove too sweeping for many earnest reformers, but none can question their importance or the value of the investigation he has made. He points out that the Poor Law medical relief is a cripple on two crutches—the general hospitals on one side, gratuitous medical work on the other—and says the whole system would break down if it were not for these helps. The hospitals supplement the workhouse and unpaid medical work the outdoor relief. But these forms of charity cannot be systematic or complete the public provision. He holds that the worst public policy is to confer personal benefit without requiring good order or obedience. It is crystallized in a case he mentions when a guardian, on a report that an applicant was a lazy loafer, who refused to work and spent all he got in public houses, maintained no one had a right to ask how he spent his money. Under the Poor Law this is a daily occurrence. Dr. McVail tells the commission that lazy drunkards are taken into the workhouse to be cleansed, fed, tended during recovery from their debauch, and let out again to return without let or hindrance to their misconduct; as women are admitted and treated for the foulest diseases, and go out to resume their career; as weak-minded girls or dissolute women enter to give birth to illegitimate children and go away again, to return after a time in the same condition. Again, phthisical cases are maintained in crowded houses, where the disease is conveyed to their families. Diabetics live on the rates and eat what they please. Outdoor relief is provided by the guardians freely for the sick and quite as freely for the drunken and immoral. Should there not be public control over the recipients of public money, and some distinction between them further than the fact of destitution? The able-bodied, infirm, victims of acute and chronic diseases, epileptics, imbeciles, deserted wives and children, widows, orphans, and so on, are all grouped together because they are destitute. The guardians must prevent their death by starvation, but have no power to help the unfortunate to regain a lost position or to control the future conduct of the unworthy or the vicious.

Mr. Shattock, at the Royal College of Surgeons, where he is pathological curator of the museum, gave a lecture on March 15 on "Tumor-like Formations of Fat in Man and Animals." Amid a wealth of information on this subject he described a little bit of human anatomy, which, I suspect, only a minority of students have examined. That is the small spherical mass, isolated from the surrounding fat, which lies upon the buccinator just in front of the masseter, and the function of which is to prevent the cheek being drawn between the jaws in the act of sucking. This "sucking cushion" persists in the adult, though in a less pronounced form, and is attached by a pedicle to the canine fossa. Moreover, it does not undergo absorption during emaciation, though most of the subcutaneous fat of the cheeks may have disappeared. Yet the adipose tissue under the microscope is identical in structure with the surrounding fat, being separated by a thin layer of connective tissue. Chemically, also, the two structures are identical. Why the cushion should withstand absorption has not been satisfactorily explained, but Mr. Shattock suggested that the mechanical function of bearing a higher degree of pressure than the surrounding fat may lead to increased vascularity, besides which there is its isolation and the narrowness of its attachment. Absorption would less readily take place through the vessels of such a pedicle than in the surrounding tissues with their more vascular connections.

Cancer of the stomach has been the subject of discussion at the Harveian Society, and, considering how frequent a cause of death it is, must always be of interest. Dr. Hale White opened with a reference to this point, saying half the cases of cancer seen in the post-mortem room begin in the stomach, but, of course, many cases do not come into the hospitals, and of those that do not all reach the post-mortem room. Three-fourths of the cases occurred between the ages of 40 and 70, and he went on to say that if gastric indigestion, first coming on after 40, was unaffected by treatment after three or four weeks organic disease was probable and the abdomen should be opened. Early diagnosis was often impossible, as advice was not sought early. Pain, present in 90 per cent., was usually constant without relation to food; weakness more profound than in dyspepsia; loss of appetite a striking feature with early nausea; free hydrochloric acid diminished, though in 10 per cent. it might be increased. In 35 to 40 per cent. blood was at some time seen in the vomits, and should be sought for in centrifugalized washings, as, too, should cancer cells. *X*-rays afforded much help. Before operation the liver and left supraclavicular glands should be examined for secondary growths. Gastroenterostomy could give relief even when the growth could not be removed.

Mr. Moynihan said surgical treatment should be advised in all stomach cases where there was obstruction, stasis or tumor, and in all cases of chronic ulcer. An exploratory incision should be for early diagnosis, not to confirm an almost hopeless one. So far as cancer of the stomach originated in ulcer it might be regarded as preventible, and therefore the importance of a history of repeated attacks of dyspepsia alike in origin, course and subsidence could not be exaggerated.

Mr. D'Arcy Power said he found hospital cases came in the late stages and private patients were unwilling to admit more than indigestion until hematemesis or secondary deposits appeared. Cancer was almost always secondary to chronic ulcer, developed slowly, and was localized for a long time to the point of origin. In early cases he found skiagrams failed to reveal thickening. Exploratory operation was to be trusted. Irritation not only led to cancer but increased its rapidity of growth. Gastroenterostomy would give rest, and if complete removal was impossible it would prevent further irritation.

Dr. H. D. Rolleston drew attention to the great difference exhibited according to the locality of the growth. At the cardiac end the symptoms were mainly constitutional—fever, anemia, debility; at the pylorus, mechanical. In cardiac cancer growth was rapid, liable to increase and to invade the left lobe of the liver. The diagnosis of pyloric cancer should be early, i.e. before a tumor was palpable, for by that time metastasis had often occurred. If an exploratory incision were made, and cancer without metastasis found,

the surgeon should go on to partial excision rather than gastroenterostomy.

Dr. Warren Low confessed he had yet to learn how to make an early diagnosis, for every one knows that the most experienced surgeons have been deceived at an operation by the similarity of an old ulcer to carcinoma. He relied chiefly on examination of the stomach contents.

Dr. Hertz emphasized the importance for early diagnosis of skiagraphy and of occult blood in the feces. He said the growth rarely gave rise to obvious malaise, and blood in the vomit was seen in less than 40 per cent. But minute bleedings were constantly occurring from malignant ulcer, so that a small quantity of blood was excreted in the feces, detectible by chemical tests. This was not the case in dyspepsia, gastritis or pernicious anemia. In simple gastric or duodenal ulcer blood might be met with in the feces, but soon disappeared under dietetic treatment. Skiagraphy he thought less reliable than other methods. Traces of bismuth might remain six hours and cast a shadow to *x*-rays, but be no proof of pyloric obstruction. Food residues obtained by tube at 8 A.M., after a last meal at 8 P.M., proved almost certainly pyloric stricture.

Mr. Crisp English stated that when a radical operation was contemplated diagnosis must be certain. He excised a bit of the diseased area, and if it proved malignant did a partial gastrectomy later.

The mortality of the profession in March has seemed heavy, influenza and pneumonia having affected young and old.

Prof. Arthur Gamgee, M.D., F.R.S., died on Monday, March 29, at the age of sixty-seven in Paris, to which city he had gone to meet a friend. He was not well on the journey. Probably influenza had begun, for it developed and pneumonia came on. He was emeritus professor of physiology at Victoria University and had held important professorships at other institutions. He was also physician at St. George's Hospital. You probably know his textbook of physiological chemistry—a standard authority.

Dr. Blakie-Smith, who died on the 29th ult. at San Remo, was consulting physician to the Royal Infirmary at Aberdeen, where he graduated and practised for many years. He had been professor of chemistry and examiner in medicine in the university.

Dr. Edgar Oswald Hopwood died on March 26. He took B.A. at Oxford with first-class honors in 1874, and proceeded to M.D. in 1882. He was for a long time the resident medical superintendent of the London Fever Hospital, and contributed the articles on "Typhus," "Scarlatina" and "Rötheln" to Fowler's Dictionary of Practical Medicine.

Dr. S. B. de Mesquita, M.D., B.S., B.Sc.Lond., who died on March 28, in his forty-seventh year, was physician to the Tottenham Home for Incurables, and had held other appointments.

Dr. F. H. Gervis, who died of pneumonia on March 24, at the early age of 37, had served as house surgeon at Thomas's and the Children's Hospitals, and took great interest in the volunteers, in which he became surgeon-captain.

Mr. Charles Edward Baker, F.R.C.S., died suddenly at the age of 44, it is thought from an accidental overdose of veronal. He was connected with the Royal Eye Hospital. At an inquest the verdict was misadventure.

At an inquest held yesterday at the London Hospital as to the death of one of the house surgeons, Dr. Angus Bewley Wilson, it was shown that he died of septicemia from a bite on his thumb, inflicted by a woman who was being gagged in order to use the stomach pump for laudanum poisoning. The coroner, Mr. Baxter, referred in a most appreciative manner to the death of this young doctor, sacrificed for a woman who, as far as the public was concerned, was worthless, for she had attempted suicide on more than one occasion. There was a vast amount of generous self-sacrifice, he said, on the part of doctors.

Headache of Puberty.—Paul Dalché describes several forms of headache occurring at the time of puberty in young girls and boys. The headache is diffuse, and occupies the frontal or occipital region. It is not migrainous nor neuralgic. In girls it may last all the time, but is generally paroxysmal, occurring at the time of the menses. It seems to be due to a sort of intoxication of the system from ovarian insufficiency. It is curable only by long-continued hygienic measures.—*Gazette des Hôpitaux.*

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

CAMP PROPHYLAXIS AGAINST TYPHOID FEVER, MALARIA, AND DYSENTERY—SUPPRESSION OF A CHOLERA EPIDEMIC—CULTIVATION OF THE LEPRA BACILLUS—HYPERTONIC SALINE SOLUTION IN THE TREATMENT OF CHOLERA—WHAT SANITATION HAS DONE FOR THE TROPICS—PIROPLASMS—FILARIA IN THE PHILIPPINES.

MANILA, March 2, 1909.

The following papers, in addition to those mentioned in my letter of February 26, were read at the meeting of the Philippine Islands Medical Association:

A paper entitled "A Resumé of Camp Prophylaxis Against Typhoid, Malaria, and Dysentery" was read by Dr. Percy L. Jones, Captain, Medical Corps U.S.A. The author stated that while the causative factors in the diseases mentioned in the title were well known, yet the practical preventative measures were usually applied only after costly experience. He further stated that he had found that better results were obtained from fuel petroleum than from crude petroleum, because the latter does not spread so well and a uniform coating is not obtained, and further, the wind shifts it and causes it to accumulate along the edges of the pool. The remainder of the paper dealt with the routine hygienic measures which are employed in camps of the United States Army at the present time.

A paper entitled "The Suppression of a Cholera Outbreak in the Provinces" was read by Dr. Allan J. McLaughlin, Assistant Director of Health. He gave a brief description of the manner in which this work is done in the Philippines and showed conclusively that where there are enough funds and a number of reasonably intelligent persons a cholera outbreak can be most easily controlled, and that without employing general quarantine measures. The plan in use in the Bureau of Health practically since 1905 has been to quarantine the houses in which cases of cholera occurred until the patient can be removed to the cholera hospital. If this is not practicable, a continued quarantine of the patient was imposed, with the further precaution of passing the dejecta into disinfectant so that there might be no danger from flies. Another important measure found to be of considerable use is to require the persons who live in cholera communities to wash their hands in disinfecting solution before eating, carbolic acid being the one solution usually employed.

The paper that probably attracted most attention at the meeting was that read by Mr. Moses T. Clegg, entitled "Some Experiments on the Cultivation of the Lepra Bacillus." Mr. Clegg started out on the basis that perhaps the organism could be grown in symbiosis, believing that the lepra bacillus derives its nutrition from the product of the tissue cells on account of the fact that it occurs almost entirely within the protoplasm. He then selected an organism resembling as closely as possible a living cell, that is, one with the nuclei and protoplasm. For this purpose amebas were grown by the method previously published by Musgrave and Clegg. It will be remembered that in order to grow the ameba successfully it is necessary constantly to add symbiotic intestinal bacteria, but in this case, instead of adding them, lepra bacilli were used, which was done by smearing the surfaces of the media containing the amebas with the pulp of a leper spleen. The first series of plates was made from a case of leprosy autopsied by Dr. Teague at the San Lazaro Hospital. The spleen in question was removed aseptically and was found to contain enormous numbers of lepra bacilli. After the plates had been smeared with this pus of the spleen, they were incubated at a temperature of 37° C. for six days. Smears were then made, stained with carbol fuchsin, decolorized, counterstained by Gabbett's method, and examined. A great number of lepra bacilli were present, together with a short, plump, acid-fast bacillus occurring mostly in the clumps of the leprosy bacilli and associated closely with the amebas. The leprosy bacilli were believed to have been carried over from the original source. Transplants were then made on fresh ameba plates and incubated for two days at the same temperature. Smears were made and stained in the same manner, and upon examination showed short, plump, acid-fast bacilli in large numbers, which showed conclusively that the organisms had multiplied. Control plates without the material from the leper spleen made at the same time, in the same manner, and with the same amebas, showed no acid-fast organisms.

After this another series was tried. The spleen was removed aseptically from a leper subject just dead. The lungs contained cavities, but there was no evidence of tuberculosis elsewhere. Smears from the spleen showed a fair number of lepra bacilli. The process described above was repeated, with similar controls and with similar results. The author of the paper stated in closing that he believed that he had found an acid-fast bacillus which was somewhat different in morphology from the leprosy bacillus, but still may be that organism, because we know nothing of the morphology of the latter on artificial media. Among the sources of error he mentioned the possibility of air contamination, which he dismissed, however, as being improbable. Second, that the acid fast bacillus originally may have grown with the ameba, but in view of the fact that control plates show no such organism it would seem to indicate that such was not the case. But the author specially mentioned the fact that it was possible that such organism might have been overlooked. Third, that there might be present as yet an undescribed acid-fast bacillus in the spleen of a leper subject. The author stated that the paper in question was merely a preliminary note and that this matter was now under thorough investigation.

Another paper that attracted considerable attention was that by Leonard Rogers, M.D., of the India Medical Service, at Calcutta School of Medicine, entitled "The Treatment of Cholera by Injections of Hypertonic Saline Solutions, with a Simple and Rapid Method of Intraabdominal Administration." Professor Rogers stated that for some years he has been studying blood changes in cases of cholera. He found by rapidly defibrinating and centrifugating the same the percentage of corpuscles showed that the corpuscles are not lost In some cases he found as many as 8,000,000 corpuscles in a cubic centimeter, with a loss of serum amounting sometimes to as much as 64 per cent. At first sight it might be expected that the loss of such a large quantity of fluid would be associated with an increase in the percentage of salts in the circulating blood, and that this may act as a conservative process by producing osmotic currents carrying into the blood rather than from it, and so checking further escape through the bowel wall in the form of water diarrhea. Further, that intravenous transfusions of normal saline fluids, such as have been used in the treatment of the disease for the last eighty years, would reduce the excess of salines in the blood and again retard the draining of fluid through the intestines. It is just this recurrence of diarrheas so commonly found in cases that have been transfused that he attributes the failure of this promising plan of treatment. From the foregoing it occurred to him that if the amount of salt content in the circulating blood was augmented by the use of hypertonic saline solutions the desired result might be arrived at. In actual practice he found that by using a solution of 1.35 per cent., to which 3 grains of calcium chloride had been added, the most gratifying degree of success was obtained. During the year 1908 the death rate at the Calcutta Medical College Hospital has been reduced from an average of 61 to 32½ per cent. In order to overcome the obvious difficulty in injecting from 3 to 4 pints of serum into the veins, he injects the fluid directly into the abdominal cavity by a specially devised cannula, with which he claims it is impossible to puncture the intestines. A study of the microscopical changes in the kidneys of patients who had died of post choleraic uremia led him to suspect that there was an actual mechanical obstruction to the circulation produced by the effusion of blood into and around the tubules. In order to test this hypothesis he measured the height required to perfuse normal saline solution through the kidney circulation post mortem, both in healthy kidneys and in those of persons who had died of choleraic uremia. The results were striking; in normal organs the pressure of from 20 to 30 mm. of mercury sufficed to run a good stream through the organs, while in the choleraic kidneys after death from uremia from 90 to 100 mm. was found necessary. In view of the fact that many of the cholera patients died of uremia and that this method of treatment aided considerably in avoiding this condition, it offered considerable hope The author formulated the following conclusions:

1. The severity of cholera is in proportion to the loss of fluid and salts from the blood, which, in all but mild cases, it is necessary to replace.

2. This can best be done by the intravenous injection of about 4 pints of hypertonic salt solution. 2 drachms to the pint, or 1.35 per cent being a suitable strength, the use of which has reduced the mortality during 1908 in the Calcutta Medical College Hospital by nearly one-half.

3. When time and staff do not suffice for the regular administration of intravenous injections they may be given intraperitoneally by the simple method described with great advantage.

4. Post choleraic uremia is associated with deficient blood pressure and should be treated by methods which raise the tension in the arterial system.

Major Probyn, D.S.O., R.A.M.C., Hongkong, read a paper entitled "What Sanitation Has Done for the Tropics," which consisted principally of an historical review of what had been done in Hongkong since British occupation. It was particularly instructive in that it showed the almost insurmountable obstacles that were put in the way of medical officers in their attempt to combat malaria fever without the knowledge of the mosquito theory.

A paper entitled "The Intestinal Worms of Women and Children in the Philippines" was read by Dr. Philip E. Garrison, Assistant Surgeon, U.S.N., and the same will be published in full in the *Philippine Journal of Science*.

Professor Martin, Imperial German Navy, read a paper entitled "Piroplasms." He gave a brief review of the work which had been done from the time that Theobald Smith in 1893 first recognized the true nature of piroplasms up to the present time. By his recent work in the Philippines he confirmed the work which has been done in Japan, showing that the piroplasm which was found among the animals there could be developed into a trypanosome.

The next paper, entitled "The Distribution of Filaria in the Philippine Islands," was read by Dr. J. M. Phalen, Captain, Medical Corps, U.S.A. He stated that the blood examination made among 7,000 native troops (Filipinos) in the Philippine Islands shows that in different sections of the Philippines filarial infection varied from ½ to 10 per cent. For instance, in the provinces of Northern Luzon the infection was about ½ per cent., while in the province of Albay the infection ran as high as 10 per cent. The next most heavily infected province was found to be Leyte, in which the infection seemed to be almost uniformly distributed throughout the island. So far, no systematic filarial examinations have been made in American soldiers, and it is not know how widely the disease prevails among them. One case of elephantiasis of the scrotum in the person of a negro soldier was under observation at the Division Hospital a few months ago.

A paper entitled "The Relation of the Indian Form of Relapsing Fever to African Tick Fever" was read by Dr. Richard P. Strong and will be published shortly in the *Philippine Journal of Science*.

DR. BULL'S FAREWELL TO HIS STUDENTS

To the Editor of the Medical Record:

Sir:—The great affection and esteem in which Dr William T. Bull was held by all students who were fortunate enough to sit at his feet will grow from more to more as the influence of time plays upon our memories and leads us back in calm retrospect to those happy days of undergraduate life. Dr. Bull possessed an exceedingly strong personality, combining those rare qualities of vast knowledge of his subject, a wide acquaintance with the hearts of his hearers, and the power of making a lasting impression upon their minds. To the writer he was a veritable tower of strength. He had the dignity and grace of royalty. There was nothing of the bizarre or blatant egoist in his nature. Never was he known to criticize in the classroom the work of other surgeons, nor to jest concerning the poor efforts of his students to master the principles of the theory and practice of surgery. He was in all respects a good fellow, and a sense of his greatness as man and teacher will grow with the coming years. None of us as yet has a proper sense of perspective as to his real worth, and any little word of appreciation must prove empty and inadequate at this time.

On May 4, 1904, Dr Bull delivered his last lecture at the College of Physicians and Surgeons, with which he had for so many years been prominently identified. Fortunately, I took careful notes of everything he said and copied them into my notebook containing his lectures His address upon this occasion follows. "I

part with pleasant company at the end of a long and agreeable voyage. I have always maintained that medical students are the best of professional students, because of the time they are willing to spend in acquiring their knowledge, the energy and enthusiasm they display, and the great interest in more or less humdrum details which they manage to maintain. It is curious how loafers from a university when taking up the study of medicine set up for themselves a new standard and show by their excellent records how they have grasped the true spirit of our noble profession. We must, all of us, always be students in order to keep up with medical progress, and, if possible, to add a bit to the knowledge of disease; and I hope to find in this respect sufficient leisure to remain one with you. I am glad my successor in teaching and those who shall come after me in my practice are graduates of these benches."

Deeply affected, Professor Bull started to withdraw from the room, but was detained by the tremendous applause which greeted him. One of the students of the graduating class, F. D. H. Coerr, arose at this point, and in a few well-chosen words presented a handsome loving cup, the gift of students in the third and fourth years. Dr. Bull replied: "I wish only for the voice, the hands, the feet, the lungs to express to you my extreme gratification for this expression of good-will. Never before have I had such a send-off, save once, and that was when suspended from college for some foolish prank, my fellow students put me aboard my train with hearty demonstrations of good feeling. I bid you all an affectionate farewell."

Dr. Bull, with bowed head, then quickly left the room, but the applause of the students continued until he was well out of the range of hearing.

Irving Wilson Voorhees, M.D.
New York.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 8, 1909.

Examination of the Feces for the Study of the Functional Condition of the Alimentary Tract in Clinical Work.—This elaborate paper by H. P. Hewes discusses the details of the Schmidt and Strasburger method which gives attention to the macroscopic and microscopic examination of the stools as distinguished from chemical analysis of the same products. The results in a test case are compared with those of a normal individual on the same diet. The object is to discover conditions of primary disturbance of the functional capacity of the digestive organs or those concerned in absorption and to determine in any given case that these organs or their functions are normal or abnormal. Normal stools indicate normal functions, but abnormal stools as to food content may be due to an altered peristalsis of the intestine from any cause. The author goes on to describe the method used, enumerating the test diet given for three or four days, following which a stool passed on the third day is observed for study. Size, color and consistency are all recorded. The stool is then mixed thoroughly with water and portions are spread on a plate for microscopic examination and a portion is ground with a pestle and a drop placed on a slide for the miscroscope, viz., for muscle fibers, starch granules, free or in cellulose capsules (Lugol's solution added), and fat remains in their various forms. The author claims that the trained observer can determine (1) whether or not the digestion of meat muscle is normal or disturbed; (2) whether digestion of starch is normal or disturbed, and (3) something in regard to the normality or abnormality of both the digestion and absorption of fats. He presents tabulated results in twenty-one cases of various maladies examined along these lines. The general usefulness of the method he regards as very great. It tells us nothing in regard to the state of proteid or carbo-hydrate absorption, its indications in regard to the utilization of these two forms of food substance, consisting only of evidences of the condition of the function of digestion of one special form of proteid substance, viz., meat fiber, and one form of carbohydrate substance, viz., starch. We are still dependent on chemical analysis for knowledge of the absorption of proteid and carbohydrates as also for exact indications of the extent of disturbance of function of fat utilization and the proportionate quantities of the various forms of fat substance present.

A Cursory Review of Surgical Methods for the Extirpation of Hemorrhoids.—T. C. Hill reviews Whitehead's suberation, clamp and cautery and ligature, giving preference to the latter. He says that statistics show that about 25 per cent. of hemorrhoidal cases are under forty years of age and for such cases the Whitehead operation, which removes the pile-bearing area, should be chosen if the patient is insistent on an absolute guaranteed cure. Still in these younger subjects it is the rule to find only one or two tumors requiring removal and to excise the lower end of the rectum for so trivial an affair seems hardly justifiable. Recurrences after small operations are not numerous, for the scar tissue left after removing one or two tumors is generally sufficient to support the remaining vessels and prevent their becoming varicose. The author has operated on over 300 hemorrhoidal cases in the last four years and has never had any abscess, fistula, stricture, fissure or ulceration follow. Operators of inexperience often overlook the smallest tumors when obscured by the bleeding incident to the operation. The result is that two or three hemorrhoids are left and after a while the patient is as much inconvenienced as before.

New York Medical Journal, April 10, 1909.

Flat Foot.—This subject is discussed at considerable length by F. E. Peckham, who considers the question of proper shoes, etc., and commends the use of a "foot exerciser" figured and described in the text. Among the complications of the condition which he says has been neglected are large callous places not infrequently found on the ball of the foot. They may be pared down, but this does not relieve much of the pain or tenderness. When callosities exist on the various corners of the feet, they are due to friction, and the friction is due to a badly fitting shoe or a shoe which may be too tight or too loose. Most of the callosities disappear on the wearing of a proper shoe. But these very tender callous places across the ball of the foot are very persistent. The pressure may be relieved by cutting a piece of gummed white felting to the proper shape and size and then cutting out a hole just the size and shape of the callous place and moistening the gummed surface and sticking it on the skin of the foot, thus relieving the tender area from such direct pressure. Also the callous may be painted every night with a mixture of salicylic acid in collodion in the strength of 4 grammes to 30 c.c. If this should prove occasionally to be too strong in the individual case and causes tenderness, it may be omitted for a week or two, when it may be continued again. Hence it is seen that the treatment of what was formerly called flat foot, but now in all but the later stages is called weak foot, has changed wonderfully in the last few years and instead of putting braces under the feet and letting it go at that, a great deal is now done in the way of rendering the joints more flexible, or developing the tone and muscular and ligamentous strength by physical exercises and vibration, by breaking up adhesions, by hot air and manipulation, and pendulum apparatus treatments and *brisement forcé*, if necessary, by regulating the footwear and by reducing the use of supporting apparatus to a minimum.

The Intraabdominal Injection of Oxygen as Studied in Animals. Report of Cases in the Human Subject.—H. D. Meeker reports his results with different series of animals. In one series the oxygen was completely absorbed in hours and in two instances not after eighteen hours. The absorption was but little hastened by increasing the intraabdominal pressure. In another series the gas was left undisturbed seventy-two hours. There was a slight increase in the pulse and respiration rate, slight rise in blood pressure the animals showed a tendency to come out immediately from under the anæsthetic, and all reactions were more prompt when the oxygen was heated. From animal experimentation the following conclusions are deduced: (1) Oxygen is completely absorbed from within the abdominal cavity. (2) It is a slight respiratory stimulant. (3) It is a slight cardiac stimulant. (4) It has but little effect on blood pressure when the pressure of the gas is moderate. (5) It tends to bring an animal out quickly from deep anesthesia. (6) It hastens the recovery of an animal after discontinuance of anesthetic. (7) A pressure of more than 1,800 mm. of water may cause collapse. (8) Oxygen tends to prevent the formation of adhesions. It does so more effectively than any inert gas. (9) It quickly changes a dark blood to scarlet in cases of anoxæmia. (10) It stimulates intestinal peristalsis. (11) It is not an irritant to the peritoneum of abdominal viscera. The so-called pure, 95 per cent. oxygen should be used. The oxygen is warmed to a temperature of about 100 deg. Fahr. by passing it from the tank in which it is compressed through a bottle containing hot water and then through a tube, preferably of metal, which is submerged in hot water. The gas enters the abdominal cavity through a rubber or blunt glass tube. The abdominal wound is closed except

at the upper or lower end, where the tube is left partly in the abdominal cavity. Interrupted stitches are placed in the peritoneum at this point, but not tied, and a pursestring loop is passed in the peritoneum around the tube. The other layers of the abdominal wall are sutured in the usual manner excepting those around the tube. After sufficient oxygen has been passed into the abdomen, the tube is withdrawn, the peritoneal stitches quickly tied, and the succeeding layers sutured. A practical rule in determining the proper amount of oxygen to be used is to distend the abdomen until liver dullness is obliterated, having previously ascertained that the liver is not adherent to the abdominal wall. Notes of personal experience in five patients are given.

Neuroretinitis Due to Typhoid Fever.—J. V. Clothier refers to one case, his patient being a girl of sixteen years. In the second week of a typhoid fever she complained that the light hurt her eyes. The following day she was unable to recognize her attending physician and her own family. She could recognize the form but not the face or color of the individuals, and complained that everything looked black to her. Ophthalmoscopical examination showed bilateral neuroretinitis. Papilla was swollen, outline obscured, vessels were partly concealed, and veins full and somewhat tortuous. The macular region was cloudy, with some faint radiating striæ to disc side of macula. The temperature gradually declined with corresponding subsidence of the papillitis and improvement of vision. Later she had a relapse of the febrile condition, but the vision steadily improved. After recovery from the fever, the ophthalmoscope showed swelling of disc had subsided, temporal and nasal margin of disc was fairly well defined, superior and inferior borders still partly obscured. In the macula were some faint radiating striæ still present. Vessels were of nearly normal caliber.

Paralytic Conditions of Childhood.—C. Rosenbeck enumerates the various forms of paralysis occurring in childhood, beginning with cerebral birth palsies, and considering cortical agenesis or defective development, the brain inflammations, anterior poliomyelitis, compression paraplegia, multiple neuritis and muscular dystrophies. Under each heading the striking features of the consequent paralysis are set forth.

Journal of the American Medical Association, April 10, 1909.

Partial Myxedema.—J. B. Nichols describes the condition of incomplete thyroid disease, or what is called by the French *myxœdème fruste*, as it manifests itself in its various forms, spontaneous adult partial myxedema, and the infantile and postoperative types. In the adult and infantile forms heredity is an important factor, and females are much more subject to the adult type than are males. The symptoms are numerous and confusing; they include asthenia, sometimes mental impairment, pain in the form of headache, backache, etc., the typical metabolic changes, trophic disorders, obesity, lowered temperature, the cardiac symptoms of the disease more or less developed, decay of the teeth, dyspnea and other respiratory symptoms, and derangements more or less extensive of the reproductive functions. These do not all appear in a single case, but in various combinations, and the diagnosis may remain obscure until cleared up by the thyroid treatment. The infantile type is distinguished from the congenitile critinism developing at or soon after birth, while infantile partial myxedema may make its appearance at any time before puberty, is more common in males than in females and may appear after an acute infection, such as measles. The most usual type is characterized by retarded development, in addition to which there are attenuated symptoms of thyroidism. The sexual organs and functions are especially affected in this retardation. Adult instances of this type are not unknown, the underdevelopment, rudimentary sexual organs and history sharply differentiating them from the adult type. Mentality may be unaffected or only slightly impaired, but sometimes there is a complete arrest. A special type of infantilism is mentioned in this connection as described by Lorain in 1870. The reported cases are nearly all in males and the specific myxedematous symptoms are absent. The specific treatment of all forms consists in the administration by the mouth and with due caution of preparations of the thyroid gland. Special care is necessary in giving the drug to patients with cardiac or arterial disease, as it may be dangerous. The best results are generally to be anticipated from this treatment, and the therapeutic test is conclusive. A case is reported.

Spelling of Medical Students.—G. Dock gives his observations of the mistakes of spelling in the examination papers of medical students. He doubts the existence of many incorrigible bad spellers and thinks that poor training is responsible in nearly all cases. He also allows for mistakes that can be easily explained by slips of the pen or mind, such as confusion of ei and ie, of single or double e, and other double letters. He also overlooks an isolated phonetic spelling, but gives a list of some of the more flagrant examples he has encountered in his experience. He also notices the misspelling of proper names and shows why he thinks there is a close relation between such mistakes as he has submitted and imperfect technical training in other respects. The causes of the condition are, he thinks, chiefly the following: (1) imperfect training in the precollegiate years; (2) imperfect scrutiny of candidates for admission to the medical schools; (3) looseness with respect to scholarly fitness all through the medical course. The fact that his observations were made on two years' students in a university shows the need of greater care as to scholarship. The habit and effort for improvement has not been required and Dock has been told by the constant perpetrator of a blunder that he did not come there to learn English. Dock thinks that a constant determined effort will be needed to alter this state of affairs.

Muscular Heat Spasm.—H. M. Welsh has frequently observed cases of muscular spasm of peculiar character due to a severe exertion in intense heat in iron workers. To make up for the loss of water by perspiration they drink large quantities, sometimes gallons, during the eight-hour period of work. There seems to be a special susceptibility in some persons, as some men will escape the cramps while others have them every hot day. They are rare in the winter months, but are apt to occur in the first warm days of the spring. Men whose work is light do not develop the symptoms, and if rest between shifts is missed for any reason the susceptible man is liable to develop the symptoms somewhat earlier in his term of work. Humidity of the atmosphere bears some relation to the condition and anything that lowers the physical vitality in a susceptible person increases the chances of an attack. The cramps are sometimes very severe and considerable force is required to prevent the contractions of the muscles, especially to extend the contracted limb. Patients sometimes say they would rather die than undergo another attack, and while Welsh says that he has never known a case to result fatally, he has had several patients who had to change their occupation on account of them. In the treatment, morphin has been largely used, but its effects are temporary. Hot packs are more effective. In all attacks, an effort is made to prevent flexion of the limbs, as that makes them less painful. Apomorphin in doses varying from 1/12 to 1/20 grain will cause immediate relaxation with, as a rule, prompt emesis, followed by marked prostration. A slap on the affected muscle will cause temporary relief, but the best treatment is probably to treat the milder cases with hot water or hot packs to avoid the prostration from apomorphin, but in all severe cases apomorphin should be given, preferably the smaller dose if it is effective and followed by strychnine 1/30 grain every four hours. He has treated between 50 and 60 of these cramps in 24 or 25 separate individuals and reports five of them briefly.

Syphilis of the Stomach.—Arthur Curtis gives an elaborate report of a case of gastric syphilis which is notable on account of the rarity with which it is diagnosed and the fact that serious complications amenable to treatment have arisen in two of the sixteen cases which have been reported. One is the case of Frankel in which death was due to extensive ulceration and peritonitis, and the other that of Flexner in which death occurred from perforated syphilitic ulcer. He also discussed the diagnosis. The synopsis of cases in the literature shows four important diagnostic factors: (1) The seat of primary involvement is, as a rule, the submucosa, the gummatous tissue invading other coats secondarily; (2) miliary gummata, sometimes with giant cells of the Langhans type; (3) *Spirochæta pallida*. These are not to be depended on according to the views of Koch and Schmorl; (4) peculiar vascular changes of high grade, resulting in partial occlusion or partial obliteration of vessels. The patient was in the surgical service of Dr. Braun at the Krankenhaus Friedrichshain, Berlin. A gastrotomy was performed and a histological examination made. The diagnosis had to exclude simple gastric ulcer and tuberculous ulcer. The former did not account for plate-like non-cicatrical thickening of the stomach wall of extensive vascular proliferation with high grade vascular occlusion. Tuberculosis was more difficult to exclude, but in addition to the epithelioid cells three factors opposed tuberculosis: First, there was no caseation; second, there was no sharp demarcation from surrounding tissues; third, there was present in each nodule a liberal number of small blood vessels. Accessory factors in the diagnosis were the negative tuberculin tests, lack of

tubercles on the serosa and absence of tubercle bacilli. Syphilis, therefore, had to be accepted as the diagnosis. Curtis emphasizes the value in this case of utilizing every available resource in diagnosis of stomach diseases. Syphilis is probably a more frequent cause of gastric tumor than is supposed, and, since the therapeutic mercurial test is so easily applied, it is at least worthy of consideration in certain selected cases. The patient made an uneventful recovery after the operation. The article is illustrated.

The Lancet, April 3, 1909.

Spontaneous Cure of Thoracic Aneurysm.—T. Oliver reports one case, the patient being a man of fifty-five years. His history dated back some twelve years. On admission to hospital he had dyspnœa, some increase of arterial tension, rapid and irregular pulse and considerable albuminuria. He died a month later, no positive diagnosis having been made. Autopsy showed chronic pleuritic thickening and effusion, alteroma of the aorta and contracted kidneys. About one inch from the aortic valve was an aneurysmal dilatation of the vessel extending almost to the origin of the left carotid and left subclavian vessels, while beyond ther was at the commencement of the descending aorta a fusiform dilatation of the vessel. The main aneurysm which was saccular had a definite daughter saccule nearly the size of a golf ball, springing from its anterior surface and pointing forward. The dilatation of the aorta extended to the root of the innominate, but not to the vessels arising from it. The interior of the aneurysm was occupied by firm, decolorized clot, but this did not extend into the innominate artery to block it. No involvement of nerves in the sac was found. The author regards especially sacculated aneurysms of the thoracic aorta as frequently cured by nature.

Pemphigus in a Nonagenarian; Recovery.—J. G. Glover's patient was a man who for five or six years had had severe attacks of nose bleed and had aged rapidly. For some eighteen months he had had eczematous patches on the left arm and left leg and for six months bullæ. The blebs were confined to the exterior aspect of the left forearm and to the outer side of the left thigh and appeared only once or twice a week. General health was excellent. The blebs later appeared on the right arm and the patient was placed on arsenic without much benefit. This was continued with morphine in small doses and the patient slowly improved. There was great dryness of the skin with some exfoliation, but otherwise the skin recovered wonderfully well. The general condition was at a lower level than before the illness. Various local applications to the skin failed to arrest the disease or allay the excessive irritation.

Graduated Rest in the Treatment of Pulmonary Tuberculosis.—E. E. Prest notes that it is possible to give the lungs approximate, not complete rest. This latter measure should be prescribed sufficiently early and for sufficiently long periods. All patients who exhibit even the smallest sign of invasion by tuberculosis must be treated with the utmost rigidity. Rectal temperatures should be taken while the patient is in bed and so long as there is any fever bed rest must be maintained. Such cases should not be put out on verandas in long chairs. Absolute silence must be maintained when during rest in bed the temperature rises over 100.4 deg. at any time of the day. If this limit is not exceeded, the patient may visit the lavatory and perform the usual duties of the toilet. The morning temperature should be taken before breakfast and it should fall at least as low as 97.8 before the patient is allowed to get up. Cases commencing with an initial hemoptysis are as a class the cases which exhibit the least fever and consequently require the least rest, but all require some rest in bed at the commencement of the bleeding. Later such patients may be allowed to exercise cautiously. Early resting prevents acute and incipient cases from becoming chronics. Patients who manifest at the outset the most violent constitutional symptoms, if they eventually survive, ultimately make the most perfect recoveries. All these suggestions apply to laryngeal lesions with double force. The cough should be controlled with opium derivatives and absolute silence must be maintained for a period of even months. So soon as the temperature falls, laryngeal patients may be allowed to exercise.

British Medical Journal, April 3, 1909.

Treatment of Gastric Ulcer by Immediate Feeding.—E. L. Spriggs gives his experience with the Lenhartz treatment, which is as follows: (1) Complete rest in bed for four weeks; (2) feeding from the beginning of the attack with small quantities of beaten-up egg and milk, increasing the amount daily; (3) icebag to the epigastrium; (4) adding to the dietary after the first week boiled rice, mince and other semi-solid and solid foods; (5) bismuth and iron in suitable form. Thirty-three patients were thus treated and a second series of thirty-four in the usual manner. The author has been able to follow up the later histories of many of his patients and comes to the following conclusions: First, the Lenhartz method is not more dangerous than treatment by nutrient and saline enemas followed by a graduated milk diet. In his particular cases the occurrence of hemorrhage was less frequent and there were no deaths; second, the pain suffered by the patient on the Lenhartz diet is less; third, the diet gives far more nourishment than can be introduced into the body by nutrient enemas who have frequently been for a long time in a state of semi-starvation or have suffered a loss of blood or both; fourth, in cases treated by this method rectal injections may be entirely avoided. This is an advantage in hospital practice and a still greater advantage in treating patients at their homes, where rectal injections are regarded as extremely unpleasant and are seldom efficiently administered.

Early Diagnosis and Treatment of Cancer of the Stomach.—W. Hale White says that cases come under observation, in the majority of cases, too late for surgical intervention, and as medical treatment is futile early diagnosis is all important. We should suspect cancer in people who come to us with symptoms of serious chronic gastric symptoms after the fortieth year, if this is their first appearance. If a course of remedies does not relieve them it is justifiable to open the abdomen, search for a tumor and remove it if found. The commonest symptoms is pain, and if it is absent we should be chary in making a diagnosis of malignancy. If cancer has developed on the site of an ulcer, the free HCl may not be diminished. In a suspected case the diminution of free HCl should be regarded as of great significance, but it must be a considerable diminution, for various diseases other than malignant will diminish it somewhat. The gastric contents should be submitted to the microscope, for occasionally free cancer cells are seen. Sometimes a few blood cells or pigment will aid in our decision. In over 60 per cent. of the cases the disease is located at the pylorus, causing a stagnation of stomach contents. Even if we cannot remove the growth or if metastases render this undesirable, much benefit often follows a gastroenterostomy for the relief of pyloric obstruction.

Another paper on the same subject is presented by B. G. A. Moynihan, whose knowledge of the subject is summed up in the following propositions: (1) Cases of cancer of the stomach when examined in regard to their previous history may be divided into three groups: (a) Cases, generally acute, in which the symptoms appear suddenly and progress rapidly; the whole history may be confined within a space of four to nine months. (b) Cases in which there is a history of one ancient attack, or of repeated attacks, due undoubtedly to the presence of a chronic gastric ulcer. (c) Cases in which there is no previous history of gastric ulcer; in some of them a condition of "ulcus carcinomatosum" may be found. (2) The acute cases are not seldom ushered in by an attack of severe hematemesis, with or without melena. It is possible that such copious bleeding is dependent upon multiple hemorrhagic erosions. (3) The importance of a history of repeated attacks of indigestion, alike in their origin, course, and termination, cannot be exaggerated. Such attacks are due to a chronic gastric ulcer, which at last becomes malignant. (4) Cancer of the stomach, in so far as it depends upon a chronic ulcer for its origin, is a preventable disorder. It is probable that two-thirds of the whole number of cases may be so classed. (5) The final attack is distinguished from former attacks by its lingering character, its rebellion against the treatment, dietetic and medicinal, which has proved helpful before, but chiefly by the presence of a profound distaste for food, anemia, and a progressive loss of weight. (6) The chemical examination of stomach contents is of little or no value in so far as early diagnosis of carcinoma of the stomach is concerned. In the later cases, when a possible diagnosis of malignancy is made on the clinical evidence, the results of repeated chemical analyses of the stomach contents afford additional evidence of considerable value. (7) Surgical treatment should be advised in all cases of stomach disorder where there is obstruction, stasis, or tumor, and in all cases of chronic ulcer; in this way early cases of carcinoma will be found, and radical treatment will be possible. (8) There are no symptoms, and there are no signs which, individually or collectively, permit of an assured diagnosis of cancer of the stomach in an early stage. In cases where there is grave suspicion an exploratory operation should be advised. Such operations should be practised to enable a diagnosis to be made in an early stage, not to confirm an almost certain diagnosis in a hopeless stage.

Book Reviews.

THE RECTUM: Its Diseases and Developmental Defects. By Sir CHARLES B. BALL, M.Ch., F.R.C.S.I., Hon. F.R.C.S. (Eng.), Regius Professor of Surgery in the University of Dublin, Surgeon to Sir Patrick Dunn's Hospital, Hon. Surgeon to the King. London: Henry Frowde, Oxford University Press, 1908.

THIS work is founded mainly upon a course of lectures delivered in San Francisco in 1902 and in London in 1903. The aim of the author being to present the material in as concise a form as possible, it was found necessary to omit historical references to the evolution of the modern methods of treatment and to the description of obsolete operations. But few statistics are given, and authorities are rarely quoted. A well-illustrated introductory chapter on the anatomy of the rectum is followed by several on the developmental defects and their treatment, in which the writer calls attention to the need of a thorough understanding of the embryological factors involved in the production of these lesions in order to formulate satisfactory surgical procedures for their cure. In the treatment of fistulæ Ball favors, in all but very complicated cases, the method first proposed in 1886 by Stephen Smith of New York, of closing fistulous wounds following incisions by sutures, instead of allowing them to heal by granulation. The important subject of rectal stricture is ably discussed, and a very practical table is appended showing the more important points of difference between malignant and non-malignant varieties. The writer details a number of procedures, original with himself, for the treatment of various lesions, including fissure, prolapse, and cancer, which appear to have stood the test of time and experience. The book is well written and is well made, and can safely be recommended as affording a clear and concise presentation of a very important subject.

GLIMPSES OF MEDICAL EUROPE. By RALPH L. THOMPSON, M.D., Professor of Pathology, St. Louis University School of Medicine. Illustrated from photographs and from drawings by Tom Jones. Philadelphia and London: J. B. Lippincott Company, 1908.

THIS is a most entertaining account of a summer tour in Europe, told in a sketchy and amusing manner, yet containing much information of interest to any medical man about to visit the schools or hospitals of the European capitals. Dr. Thompson visited Christiania, Copenhagen, Stockholm, St. Petersburg, Berlin, Vienna, Budapest, Paris, London, and Liverpool, and kept his eyes very wide open. The account he gives is, as we have said, more or less sketchy, yet accurate so far as it goes. An appendix contains a list of the medical courses most frequently taken by English and American physicians in Berlin, together with the fees, and an indication of which is given in English, or at least by English-speaking instructors. In another appendix is given a brief account of the German universities.

PRACTICAL BACTERIOLOGY, BLOOD WORK, AND ANIMAL PARASITOLOGY, including Bacteriological Keys, Zoological Tables, and Explanatory Clinical Notes. By E. R. STITT, A.B., Ph.G., M.D.; Surgeon, U. S. Navy; Graduate London School of Tropical Medicine; Instructor in Bacteriology and Tropical Medicine, U. S. Naval Medical School; Lecturer in Tropical Medicine, Jefferson Medical College. With 86 Illustrations. Philadelphia: P. Blakiston's Son & Co., 1909.

THIS is a thoroughly practical manual of laboratory instruction in the subjects mentioned in the title, written by a man who knows his subject and who has the happy faculty of imparting his knowledge in few words in a clear and comprehensible way. The work is by no means cyclopedic, but includes only the methods which practical experience has shown to be the best adapted to the requirements of a satisfactory clinical laboratory diagnosis. The subject-matter is treated in four parts: I. Bacteriology; II. Study of the Blood; III. Animal Parasitology; IV. Clinical Bacteriology and Animal Parasitology of the Various Body Fluids and Organs. An appendix contains sections on Preparation of Tissues for Examination in Microscopic Sections, Mounting and Preservation of Animal Parasites, Preparation of Normal Solutions, and a List of Diseases of Unknown Etiology. The description of the various micro- and macro-parasites is systematic and is greatly facilitated by the classifications and keys which precede each section. In addition to the parasites, the mosquitos, flies, and other insects known to be the agents of transmission or the alternate hosts of the microparasites are described and figured. The book will be found useful not only as a guide for the laboratory worker, but as a work of reference to the pathogenic parasites and their insect carriers.

DER SCHIFFSARZT. Leitfaden für Aerzte und Kandidaten der Medizin, mit Angabe der Reedereien ihrer Linien und Anstellungs-Bedingungen und Berücksichtigung aller einschlagigen Fragen. Von Dr. M. BRENNING und Dr. E. H. OPPENHEIMER. Mit sechs Textfiguren. Berlin. Verlag von August Hirschwald, 1909.

THIS book may be called the ship-surgeon's vade mecum, for it contains about everything that the ship-surgeon or one wishing to become such can possibly need or wish to know. It is, of course, intended primarily for the German physician, and the information it gives regarding the various lines refers naturally only to those employing German surgeons, but what it has to say concerning the duties of the ship-surgeon and the advantages and disadvantages of his calling is of general application. Every one contemplating entering the medical service of the mercantile marine under any flag, and even the already more or less experienced ship-surgeon, will find much of interest and more of practical utility in this little book, which is evidently written by men who know all the ins and outs of the service and tell what they know in a plain and straightforward way. The pictures illustrate the gymnasiums on three of the German steamships, and the drug-room, the hospital, and the surgeon's cabin on the *Kronprinzessin Cecilie* of the North German Lloyd

BACTERIAL FOOD POISONING. A Concise Exposition of the Etiology, Bacteriology, Pathology, Symptomatology, Prophylaxis, and Treatment of So-called Ptomaine Poisoning. By Prof. Dr. A. DIEUDONNÉ, Munich. Translated and Edited, with Additions, by Dr. CHARLES FREDERICK BOLDUAN, Bacteriologist, Research Laboratory, Department of Health, City of New York. Authorized Translation. New York: E. B. Treat & Company, 1909.

THE importance of the early recognition of food poisoning, whether occurring in isolated cases or affecting large numbers of individuals, is so very great that all practitioners should be entirely familiar with the manifestations of the condition and the circumstances under which it may arise. The literature of the subject though not very extensive is for the most part not easy of access to the general reader, and Professor Dieudonné has performed a useful service in thus summarizing what is known concerning this form of intoxication. Formerly regarded as the direct result of the ingestion of the toxic products of putrefaction, it has now been shown that in most instances specific bacteria are responsible for the symptoms. The first section of the book is devoted to the poisoning caused by meat—usually associated with *B. enteritidis, B. paratyphi, B. proteus, B. coli,* or *B. botulinus*—the next to poisoning through fish and molluscs, the following two to that due to cheese, ice cream, etc., and in the closing sections potato poisoning, that occurring through canned goods, and the metallic poisons are considered. The translator has performed his task with his usual skill, and the additions for which he is responsible render the book thoroughly satisfactory for American readers. The little volume is to be heartily commended to the attention of all medical men.

PRÉCIS DE STOMATOLOGIE. Par J. REDIER. Professeur à la Faculté libre de Médecine de Lille. Tome premier. Paris: F. R. de Rudeval, 1909.

THIS is not a treatise on stomatology, as we understand the word in America, inasmuch as it treats of those oral diseases only which are of dental origin. It is, therefore, not of especial interest to physicians, although certain chapters may be read with some profit by the general practitioner. The sections of the book dealing with the development of the mouth and teeth, dental anomalies, dental orthopedics, and dental caries are of value, though they contain nothing new.

ÉTUDES SUR LA PHYSIO-PATHOLOGIE DU CORPS THYROÏDE ET DE L'HYPOPHYSE. Par les Drs. LEOPOLD-LÉVI et HENRI DE ROTHSCHILD. Preface de M. CH. ACHARD, Professeur Agrégé à la Faculté de Médecine; Médecin de l'Hôpital Necker. Avec 4 Figures et 9 Planches. Paris: Octave Doin, Editeur, 1908.

THIS volume contains eight chapters, on various conditions connected with the thyroid gland. There is a lengthy introduction of nearly seventy pages, which is, perhaps, the most important part of the book. The studies and problems connected with the physiology and chemistry of the thyroid are barely alluded to; and the literature referred to is almost entirely French. The work is readable, but does not materially add to what has been known of the subject for many years.

Society Reports.

ASSOCIATION OF AMERICAN MEDICAL COLLEGES.

Nineteenth Annual Meeting, Held in New York, March 15 and 16, 1909, under the auspices of the New York Academy of Medicine.

THE PRESIDENT, DR. ELI H. LONG, UNIVERSITY OF BUFFALO, IN THE CHAIR.

Committee on Medical Education.—This committee recommended (1) that the Association place itself on record by emphasizing the importance of the standard public high school, as evaluated in its schedule, as a natural education basis on which to build, when it becomes feasible, additional educational requirements, and that the colleges of the Association pledge themselves to a strict enforcement of the present standard.

(2) That the Association recognizes the importance of standardizing the secondary educational system of the country, and places itself on record by asking the individual colleges, members of the Association, to pledge themselves to lend their influence and support to all the educational forces looking to this end.

(3) That the Association, in accordance with its position favoring additional preliminary education beyond the present standard as a prerequisite to a medical course as soon as practicable, endorses and encourages the combined baccalaureate and medical courses given by many universities.

Committee on Equipment.—This committee did not, in the main, depart from the report made by the secretary last year, except in that it elaborated on the buildings to some extent. The equipment standard adopted last year has since then been adopted by the American Confederation of Reciprocating Examining and Licensing Medical Boards and also by the Michigan State Board of Registration in Medicine.

Committee on Curriculum.—This committee, which considered only the subjects usually taught in the first two years of the medical course, presented the following schedule as the final result of the work done by the committee since its appointment in 1907:

	Total.	Didactic.	Laboratory.
Gross anatomy		120	420
Microscopic anatomy	750	30	105
Embryology		30	45
Inorganic chemistry		60	120
Organic chemistry	420	60	45
Physiological chemistry		60	75
Physiology	240	165	75
Bacteriology		30	105
Hygiene	405	30	
Pathology		45	195
Pharmacology	185	40	145
Materia medica and pharmacy.		?	?
	2,000	2,000	

(Materia medica and pharmacy may be taught under the head of pharmacology or separately, as desired.)

The last two years of the course will be reported on at the next meeting of the Association.

Committee on Medical Teaching.—This committee concerned itself entirely with pedagogical problems, such as the training of the medical teacher and the methods of instruction. The committee was of the opinion that the student was not a proper teacher to be placed in charge of any phase of educational work; that no one should be placed in charge of any work who had not had at least two years of experience in the subject he was called on to teach. The laboratory man should not be engaged in the general practice of medicine, and the teacher should be working in the line he was called on to teach: that is, an internist should not teach applied anatomy; the surgeon should not teach therapeutics. The teacher should present those simple things that the student will be called on to use and not the impossible things that he never will employ. The medical teacher should keep in mind self-effacement rather than self-exploitation. With regard to the State board examinations, the committee was of the opinion that they tend to encourage quiz compend methods, emphasizing the memorizing of facts rather than the development of knowledge and judgment. The committee viewed with favor the introduction of practical tests in such examinations. Mass instruction was condemned; individual instruction was recommended as being pedagogical and valuable; the student should not be deluged with lectures and work that consumed more time than he could well afford to spend in college, thus shortening the hours devoted to study.

The following resolutions were adopted:

Resolved, That it is the opinion of the Association that State board examinations should be divided into two parts, the examination in the laboratory sciences being offered at the end of the second year of the course, and that State boards enter into such an arrangement wherever this is legally possible.

Resolved, That the Association favors practical and laboratory examinations as substitutes for part of the written examination now almost universally employed, and that State examining boards be requested to adopt such examinations, if possible.

Medical Education.—DR. HENRY S. PRITCHETT, president of the Carnegie Foundation for the Advancement of Teaching, said that the very first thing of interest in connection with medical education was the different plane on which it stood with respect to support, as compared with the other great technical schools, where instruction is carried on under the grants coming from great endowments, whereas the medical school is of necessity on a commercial basis, depending for its teachers almost wholly on medical practitioners who give their services free, and for financial support on the income of its students. The medical profession has not brought home the claims of medical education in the same way that other professions have brought home their claims. So far as the layman was concerned, he has the right to demand that the medical practitioner be grounded in the sciences that are fundamental to medicine. Some pre-requisite in education is absolutely essential for medicine, but just what that shall be seemed to be undetermined. It was necessary to know, first, what can be gotten in the various States and what can be enforced. The Carnegie Foundation was now collecting material for an exhaustive report on this very question, and expected to report within the next six or eight months. Until this evidence was obtainable it was considered unwise to attempt to set any standards for admission to the medical school. The general educational system of the country must be investigated before standards can be set. The standards in various parts of the country differ so much that any attempt to set a standard without taking into cognizance these variations would fail. In the meantime it was advised that colleges enforce their present standards honestly, giving such aid to the Foundation in carrying on its work as was possible.

Combined Course.—Professor WILLIAM H. CARPENTER, Columbia University, outlined the course adopted by Columbia some years ago with reference to the combined course not only in medicine, but in other professions. He insisted that rigid supervision of the work was essential to successful administration of such a course, and pointed out that not all colleges were in a position to give the course. The student must be placed on a definite basis of

study, and a definite requirement must be laid down, so that a definite result will accrue. As a rule, the baccalaureate degree of the American college means nothing, often not as much as the entrance requirement of the good colleges. Therefore, it is absolutely necessary that the combined course must be administered in such a manner that it will stand for something. The student who proposes to take the combined course should be required to take in addition to his regular work such studies as will give him a broader and sounder foundation for his professional studies. The intending student of medicine should have physics, chemistry, elementary biology. So far from weakening the baccalaureate degree, it strengthens it because it makes the degree much more difficult of attainment, and it strengthens the professional school by giving to it a better student, a man better prepared to take up his professional studies. Dr. Carpenter also mentioned the so-called Rochester plan, which permits the senior student in the science school to take the first year of the medical course while still registered as a college student, returning to his college for his degree at the completion of the first year medical work, thus getting the two degrees in seven years. He did not advise that every college be permitted to offer the combined course, but only such institutions as were prepared to do so by reason of superior facilities.

Present Status of Medical Education.—Dr. Frederick C. Zapffe, University of Illinois, reviewed the gradual evolution of medical education, and pointed out that it was better and to the best interests of education in general for the medical school to demand and enforce an entrance requirement that was within reach, and not one that was not obtainable. It was shown what the influence of the Association had been in the matter of raising the requirements and particularly of standardizing them, not only for entrance, but in course of study and graduation and equipment. By demanding more of the prospective student of medicine than he could possibly offer, because of the status of general education in his State, he was forced into the poorer, weaker, inefficient medical school, thus defeating the very objects for which standards are made. The present high school standard was deemed about as high a standard as it was possible to enforce, except in individual instances and by certain colleges, but for the mass of students, the high school standard was high enough, for the present at least. The honest administration by all medical colleges of the requirements now in force was considered a decided step in advance, and in that direction much had been accomplished by the Association. The combined course was commended very highly, and all prospective students of medicine were urged to take such a course, if possible. In order to relieve the congestion of the medical curriculum, it was suggested that the course of study be lengthened to five years, and a tentative course of that kind was outlined, in which the student would receive instruction also in physics, biology and botany as well as in the subjects now contained in the curriculum. A six-year course was also proposed, a course of two kinds, leading to two different sets of degrees; first, a practical course, where the student devotes six years to medical study, leading to the degrees of B. S. M. D.; second, a scientific course, two years being taken in the science school and four in the medical school, leading to the degrees of B. S. M. B., a course which the prospective research worker might elect to take. A third course might consist of four years in the medical school after graduation from the high school, the degree of L. M. being granted when the candidate secures his license to practice.

Five-Year Course.—Dr. John Rogers, Cornell University Medical College, favored a preliminary fifth year for the purpose of providing instruction in subjects in which the high school graduate is not proficient or is lacking and to relieve, in small measure at least, the congestion of the medical curriculum. This preliminary fifth year would include teaching in chemistry, medical physics, with physical chemistry, biology and comparative anatomy. Electives might be provided for advanced students and opportunities for research. This fifth year must not be elective, inasmuch as it is intended to provide the student with a solid foundation for medicine. The principles on which the science and art of medicine rest are all that the colleges could expect to teach. They do this now in four years, but can do it better in five. Such a course was not a remote possibility, but was an immediate necessity, and if the colleges that now demand the highest preliminary education possible escape the dilemma long, it will be only because of radical reforms in the academic colleges.

Addresses were also delivered by the president, Dr. Long, who discussed the functions of the medical school, and by Dr. John A. Wyeth, president of the New York Academy of Medicine, who described very vividly and entertainingly the medical student of 1867, narrating his early experiences as a medical practitioner.

Officers Elected.—*President,* Dr. George Howard Hoxie, University of Kansas; *Vice-Presidents,* Drs. David Streett, Baltimore Medical College, and J. A. Witherspoon, Vanderbilt University; *Secretary-Treasurer,* Dr. Frederick C. Zapffe, University of Illinois; to fill vacancies on *Judicial Council,* Drs. Egbert LeFevre, University and Bellevue Hospital Medical College, and Wm. P. Harlow, University of Colorado. Baltimore was selected as the next place of meeting, March 21 and 22, 1910.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 4, 1909.

Dr. John A. Wyeth in the Chair.

This meeting was held under the auspices of the Section on Otology.

Sinus Thrombosis of Otitic Origin and Its Relation to Streptococcemia.—Dr. Emil Gruening read this, the paper of the evening. He said that the microorganisms which caused purulent inflammation of the middle ear were chiefly the *Streptococcus pyogenes* and *Streptococcus mucosus.* In almost 70 per cent. of the cases the streptococcus was found. The pneumococcus and the staphylococcus played no rôle of importance. Thrombosis of the lateral sinus as a result of purulent middle-ear disease was often associated with systemic infection. In many cases it had been shown that streptococci circulated in the blood. In the last ten cases of sinus thrombosis occurring in the otological service at Mt. Sinai Hospital, the blood cultures were made under the supervision of Dr. E. Libman. Blood was taken from the median vein immediately after ligation of the internal jugular vein. The blood cultures were positive in seven cases and negative in three. In five cases *Streptococcus pyogenes,* in one *Streptococcus mucosus,* and in one other *Bacillus proteus* were found. Of the ten consecutive cases occurring in Mt. Sinai Hospital, eight recovered and two died. All the cases having streptococcemia recovered after ligation of the internal jugular vein. The diagnosis of thrombosis was, however, not made from the blood culture, but from the clinical data. Still, a positive blood culture could be advantageously used in the diagnosis of obscure cases of sinus thrombosis in which the aural symptoms were not very marked. In two cases admitted to the medical wards with high fever, systemic infection, and without prominent ear symptoms, Dr. E. Libman was able to diagnosticate thrombosis of the lateral sinus, and this diagnosis was made chiefly because of the presence of streptococcus in the blood, after excluding other foci than the ear. In these two cases the lateral sinus was found to be thrombosed, and the patients recovered, one with and one without ligation of the jugular.

Dr. Edward B. Dench said that he had had 23 cases of sinus thrombosis in which the internal jugular was excised. Of these 14 were cured and nine died, one of hemorrhage into the spinal canal, one of general pyemia, three of pneumonia, one of gangrene of the lung, one of malnutrition, one of hemorrhage into the cerebellum, and one of gangrene of the neck. In his experience the differential blood count had been rather unsatisfactory; he had seen a number of cases of sinus thrombosis in which the differential blood count showed no great departure from the normal. In cases of jugular thrombosis the tenderness, in his experience, had been in the lymphatic glands and not in the vein itself. The enlargement of the lymphatic glands along the course of the vein he regarded as one of the clinical signs of sinus thrombosis. Dr. Dench mentioned 48 cases of sinus thrombosis; also 28 cases of sinus thrombosis, in which the jugular was not excised, and of which 24 were cured and only four died. In all of these cases the clot was removed from the sinus by operative interference, but it was not necessary to interfere with the jugular. These statistics showed that in a certain proportion of the cases excision of the jugular was not necessary to cure sinus thrombosis.

Dr. Frederick Whiting said he understood that the question raised was: Given a suppurating ear and streptococcus in the blood, was one justified in making a diagnosis of a clot in the sinus? It did not necessarily follow that because there was a streptococcemia present in such cases there were clots in the sinus; there had not yet been a sufficient number of cases reported to prove that it necessarily followed. Dr. Gruening's findings were strongly corroborative of the view that clot was found in the sinus where there was no streptococcemia. It would seem that if one could eliminate from the patient's condition endocarditis, erysipelas, cryptic throat, and other suppurating foci, and if one could find a focus in the ear, and streptococci were found in the blood, then one was justified in looking for a clot in the sinus.

Dr. Libman said that, with Dr. Celler, he had been engaged in the study of infections of otitic origin by means of blood cultures for about ten years. There had been much difference of opinion among authorities as to the most common infecting organism in acute otitis media. More recent investigators had found the streptococcus most frequently, whereas the early writers considered the pneumococcus the most common infecting agent. In their study of about 360 cases they had found *Streptococcus pyogenes* most frequently, *Streptococcus mucosus* less frequently, and the pneumococcus in the smallest number of cases. Notwithstanding the fact that the pneumococcus had been found frequently by many authorities in the middle ear and notwithstanding the fact that they had found the organism in a certain number of cases, there were hardly any records of sinus thrombosis being due to this organism. With regard to the conditions under which bacteria were found in the blood in cases of acute otitis media, with or without complications, in their experience they had not found bacteria present in cases of pure otitis media, mastoid disease, extradural abscess or brain abscess. Their positive results had been in the cases of sinus thrombosis and meningitis. In some cases of sinus thrombosis the blood culture was negative. They were not yet able to explain all the negative results. It was very unusual to find streptococci in the blood in cases of erysipelas. They had no trouble from a possible confusion because of an angina. A positive blood culture was valuable if there was doubt as to the existence of a sinus thrombosis after the patient had been operated upon for mastoid disease. The most valuable field for the blood culture studies was the border line cases. If a patient had been operated upon for sinus thrombosis and the jugular vein was tied, and the bacteria disappeared from the blood, it was clear that the entrance of infection to the system had been stopped. A negative blood culture in these cases was of great value, for it helped decidedly in excluding an infective endocarditis. It was interesting to know how quickly the blood got rid of the bacteria after the clot had been removed, or after the jugular vein had been ligated.

Dr. Arthur B. Duel believed that the conclusions reached by Dr. Libman were altogether too sweeping, and that further investigation would teach them not to interpret results of examinations of the blood as definitely settled. Dr. Duel was inclined to doubt the advisability of accepting the presence of bacteriemia in a case with suppurative otitis as sufficient cause for invasion of the sinus, in the absence of some clinical symptoms.

Dr. John D. Richards did not believe that the presence of streptococci in the blood necessarily meant a thrombosis in the sigmoid sinus, for he had seen cases clinically in which there was merely a purulent phlebitis, yet sinus thrombosis was present and metastases had occurred; therefore, to assume a clot in the sinus merely upon the bacteriological findings that streptococci were present was doubtful.

Dr. Joseph A. Kenefick reported two cases which occurred in infants to illustrate the difficulty of applying blood cultures. When cases occurred in infants under three years of age, and where there was a complicating pneumonic process in the lung, and where both ears were involved, the question of diagnosis became a very serious problem. In the first case the diagnosis was made postmortem. In the second case a blood culture was made and was negative.

Dr. Kopetzky said that the question as to whether or not streptococci were to be found in the blood in other conditions besides sinus thrombosis was another side of the question which must be satisfactorily settled; until it was settled, the final diagnostic value of Dr. Libman's findings must be accepted with reserve.

Dr. Gruening said that only ten cases of sinus thrombosis had been reported, and these were diagnosticated by the clinical symptoms alone. Blood cultures were made in these cases and it was found that positive results were more frequent than negative results. The patients who had streptococci in the blood recovered after ligation of the jugular vein.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of Maryland.

December, 1908.

ANATOMY.

1. Describe the acetabulum.
2. Describe and give the anatomical relation of the appendix vermiformis.
3. Give attachments, action, and nerve supply of the following muscles: Digastric, gastrocnemius, rectus oculi externus, triceps extensor cubiti.
4. Describe the valves of the heart.
5. Locate and describe the spleen.
6. Name the opening into the pharynx.

PHYSIOLOGY.

1. Give functions of spinal cord.
2. (*a*) Describe the normal flow of blood through arteries, capillaries and veins, and factors which cause the flow in each. (*b*) What is the total quantity of blood as compared with weight of the body? (*c*) About what time is required for a complete circulation of the blood through the body?
3. What are tonic and clonic muscular contractions? Give examples.
4. Where is bile formed? How does it reach the digestive tract? What are its functions?
5. Describe the functions of the thyroids and parathy-

roids, including a consideration of the effects of their removal.

6. Describe the condition of food upon entering and upon leaving the stomach and the digestion which takes place there.

CHEMISTRY.

1. Define oxidation, combustion, crystalloid, and colloid, and give an illustration of each.

2. Name three chemical substances in frequent use as general anesthetics; give the chemical composition (formula) and general properties of each, and state what they are chemically.

3. Give the chemical composition (formula) of peroxide of hydrogen and permanganate of potassium; give the general properties of each, and state to what element they owe their antiseptic and disinfecting qualities.

4. What, chemically, is Paris green? Give in detail a reliable test for its detection in a supposed case of poisoning from it.

5. Describe in detail the various steps in an ordinary examination of the urine.

6. Give in detail a reliable test for the detection of free hydrochloric and lactic acids, respectively, in specimens of gastric contents.

MATERIA MEDICA.

1. Name three drugs which may be used to produce diaphoresis.

2. Arsenic: its preparations and the dose of each.

3. Name two galactagogues, two cholagogues, and two sialagogues.

4. Codeine, atropine, eserine: give the source and dose of each.

5. Name the physiological antagonists of pilocarpine, morphine, and phytolacca.

6. Santonin, creosote, elaterium, sulphonal, podophyllum, picrotoxin: give the dose of each.

THERAPEUTICS.

1. Ergot: its therapy.

2. How would you determine the proper dosage for a child?

3. Scoparius: its active principle, dose and physiological action.

4. Define the terms *ad libitum, compositus, fiat, chartula, macero, misce, pro re nata, quantum sufficiat,* and *ter in die.*

5. Cocaine: its derivation; symptoms and treatment of an overdose.

6. Write a prescription for an adult for one dozen pills containing iron, arsenic, and strychnine, using Latin terms and giving directions for taking.

PATHOLOGY.

1. (*a*) Give the gross pathology as regards the lungs of acute miliary and chronic ulcerative tuberculosis, respectively; describe in detail the method of staining the tubercle bacillus in the sputum. (*b*) Give the gross pathology of two diseases of the urinary tract associated with hematuria; give in detail the method of staining of the organism, if any, associated with each. (Candidate may answer either question (*a*) or question (*b*) above, but must not answer both.)

2. Give the gross and microscopic pathology of the disease you would expect to find in an elderly woman suffering from an offensive bloody vaginal discharge.

3. Explain what is meant by the terms physiological and pathological leucocytosis, respectively, and state whether a leucocytosis is present in the following diseases: Typhoid fever, malarial fever, appendicitis, acute miliary tuberculosis.

4. Describe the change one would expect to find in the appendix and surrounding structures in a case of gangrenous appendicitis. Give reasons for the formation of an abscess or the onset of general peritonitis in such a case.

5. Give in detail the pathology of a severe case of tertian malarial fever and describe in detail the parasite involved. What insect acts as an intermediary?

6. Give in detail the pathology of the blood in a case of pernicious anemia and one of chlorosis, respectively.

PRACTICE.

1. Define (*a*) Endemic disease. (*b*) Vocal fremitus, and state its significance in pulmonary diseases. (*c*) Argyll-Robertson pupil, and name the disease in which it is one of the diagnostic symptoms. (*d*) What is the significance of the patella reflex as a sign of disease? (*e*) What is the diagnostic significance of Cheyne-Stokes respiration?

2. (*a*) What are the characteristic symptoms of Graves' disease? (*b*) Give the differential diagnosis between catarrhal pneumonia and croupous pneumonia; (*c*) between gastric cancer and gastric ulcer.

3. (*a*) How would you treat acute nephritis accompanying or following scarlet fever? (*b*) How would you treat herpes zoster? (*c*) Describe treatment of acute inflammatory articular rheumatism.

4. Give differential diagnosis between spasmodic and membranous croup.

5. How would you diagnose and treat intestinal perforation in typhoid fever?

6. Differentiate between neuritis and neuralgia.

SURGERY.

1. Give the signs, symptoms, and treatment of acute synovitis; of chronic synovitis.

2. Give the details of the operative treatment of gunshot wounds of the stomach and intestines.

3. Give the symptoms of enlargement of the prostate, with a description of its surgical treatment, palliative and radical.

4. Describe the more important effects of nasopharyngeal growths and nasal affections upon the ear.

5. Describe pterygium and its surgical treatment.

6. Give the indications for nerve suture and describe the operation.

OBSTETRICS.

1. Describe cephalic version by the internal and external methods.

2. Give the management of a face presentation.

3. Write short articles on two of the important toxemias of pregnancy.

4. What are the dangers to be avoided in performing a dilatation of the cervix and a curettement of the uterus?

5. Give etiology, classification, and treatment of perineal tears.

6. Give indications for a suspension of the uterus and the various steps of the operation.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF MARYLAND.

December, 1908.

ANATOMY.

1. The *acetabulum* is a deep, hemispherical depression in the os innominatum. It is made up of all three bones comprising the os innominatum, viz.: the ilium, ischium, and pubis. It looks downward, outward, and forward. It is made deeper by a marginal rim, which does not go completely around it. At the bottom of the cavity is a circular depression, called the fossa of the acetabulum, which lodges a mass of fat, and to the margins of which are attached the ligamentum teres. There is a deep notch on the lower border, called the cotyloid notch, which is converted into a foramen by a tough ligamentous band which passes across it; through this foramen the nutrient vessels and nerves enter the hip joint.

2. The *vermiform appendix* is a long, narrow, musculomembranous tube which is given off, as a rule, from the inner side of the posterior wall of the cecum; but its position, as well as its size and direction, are very variable, usually it is about 2 or 3 inches in length by about $\frac{1}{8}$ to $\frac{1}{4}$ inch in diameter, but it may vary in length from $\frac{1}{2}$ to 9 inches. It generally points upward and inward (in a line pointing toward the spleen); it may be found in almost any relation to the cecum and ascending colon. It consists of four coats: the serous (usually completely covering the appendix, and making a mesentery), the muscular, submucous, and mucous; this last contains blood vessels, nerves, and lymphatic glands.

3. *Digastric.* The posterior belly arises from the disgastric groove on the internal surface of the mastoid process of the temporal bone; the anterior belly, from a depression on the inner surface of the lower border of the inferior maxilla, near the symphysis. These two bellies are connected by a central tendon which perforates the stylo-hyoid, and is bound down to the greater cornu of the hyoid bone by a process of fascia. *Action*:—It raises the hyoid bone and depresses the lower jaw. *Nerve supply*:—The posterior belly is supplied by the facial, the anterior belly by the mylohyoid branch of the inferior dental.

Gastrocnemius:—The inner head arises from a depression on the upper and back part of the inner condyle of

the femur and the adjacent part of the femur; the outer head from an impression on the external surface of the outer condyle, and from the posterior surface of the femur immediately above the condyle, It unites with the tendon of the soleus to form the tendo Achillis, which is inserted into the lower part of the posterior surface of the os calcis. *Action*:—It flexes the knee, raises the heel, and extends the ankle. *Nerve supply*:—Internal popliteal.

Rectus oculi externus:—The upper head arises from the outer margin of the optic foramen; the lower head from the lower margin of the sphenoidal fissure and the ligament of Zinn. It is inserted into the sclerotic coat about 3 or 4 lines from the margin of the cornea. *Action*:—It turns the eye outward. *Nerve supply*:—The sixth cranial nerve (the Abducens).

Triceps extensor cubiti:—The long, or middle, head arises from a depression on the axillary border of the scapula immediately below the glenoid cavity; the external head from the root of the great tuberosity on the posterior surface of the humerus, and the upper part of the musculospiral groove; the internal head from the posterior surface of shaft of humerus, below musculospiral groove, and the internal and external muscular septa. It is inserted into the back part of the upper surface of the olecranon process of the ulna. *Action*:—It extends the forearm. *Nerve supply*:—The musculospiral.

5. The *spleen* is situated in the back part of the left hypochondriac and epigastric regions, being covered by the ninth, tenth, and eleventh ribs, on the left side, It is of an oblong, flattened form, the external surface being convex; on the inner surface is a vertical ridge dividing it into two parts, the posterior of which is applied to the outer surface of the left kidney, while the anterior one receives the tail of the pancreas, and lies against the cardiac end of the stomach. Near this ridge is a fissure,*the hilum*, where the vessels enter. The anterior border is notched, and the lower end is pointed and rests on the costocolic ligament, situated in the left hypochondriac region. It is covered by peritoneum, except at the hilum, where it passes forward and inward in a double line enclosing the vessels, as the gastrosplenic omentum, to the fundus of the stomach. It usually measures 5 by 3 by 1 or 1½ inches, and weighs about 7 ounces.—(From *Aids to Anatomy*.)

6. *The openings into the pharynx* are: The two posterior nares, the two Eustachian tubes, the mouth, the larynx, and the esophagus.

PHYSIOLOGY.

1. *The functions of the spinal cord* are: (1) The conduction of nerve impulses; (2) reflex action; (3) coordination; it also contains special centers which preside over definite functions.

2. (*a*) The circulation of the blood is regulated in (a) *the arteries*, by: (1) the elasticity and tone of the arteries; (2) the force and frequency of the cardiac contractions; (3) the resistance in the capillaries; (b) in the *capillaries* it is regulated by: (1) the action of the heart; (2) the action of the arteries: (c) in the *veins* it is regulated by: (1) the action of the heart; (2) aspiration of the thorax; (3) the contraction of the muscles, and (4) slightly by the valves in the veins.

(*b*) The total quantity of blood is supposed to be about one-thirteenth of the weight of the body.

(*c*) The time required for a complete circulation of the blood through the body is about twenty-three seconds.

3. In *tonic muscular contraction* the muscle remains for some time in a state of rigid contraction. In *clonic contraction* the muscle alternately contracts and relaxes. Tonic muscular contraction occurs in tetanus; clonic, in an ordinary convulsion.

4. (*a*) Bile is formed in the liver cells.

(*b*) The bile is conveyed from the liver by the bile capillaries which eventually form the hepatic duct; it (the bile) is stored in the gall bladder, whence it flows through the cystic duct and the ductus communis choledochus into the duodenum, about three inches below the pylorus.

(*c*) *The functions of the bile* are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

5. The *function of the thyroid* is not definitely settled; (1) it has some trophic function, regulating oxidation in the body, and it is supposed to have also a special influence on the vasomotor nerves, the skin, the bones, and on the sexual functions; (2) it is supposed to antagonize toxic substances; and (3) it produces an internal secretion.

Removal of the thyroid gland causes mental and bodily dullness and apathy, tremors, twitchings, overgrowth of the connective tissues, and development of fat; the hairs fall out, and the patient becomes unwieldy and clumsy in both body and mind. The complete removal causes death in most animals, and it is not considered justifiable in man.

Removal of all the parathyroids causes death from acute tetany. Their exact function is unknown, but it is supposed that some of the evil effects attributed to removal of the thyroids is really due to the removal of all the parathyroids as well, and that if the parathyroids are left (with their blood supply intact) these results will not ensue.

6. On *entering the stomach* the food is already crushed, mixed with saliva, and reduced to a pulp; it is rendered slightly alkaline, and a small amount of the starch has been converted into maltose; the proteids and fats are unaltered.

In the stomach, where the contents are rendered acid, conversion of starch into sugar ceases, connective tissue of fats is dissolved, and fats are set free. Proteids are dissolved and peptones formed. The albuminous foods are dissolved for the most part, and a grumous mixture of peptones, liquid fats, and starches is formed, which is termed chyme, and is gradually passed through the pylorus into the intestine.

The contents of the stomach at the close of gastric digestion are: Water, inorganic salts, acidified proteids, peptones, liquid fats, starch, cellulose, and the indigestible residues of various foods.

CHEMISTRY.

1. By *oxidation* we mean the act of union of oxygen with another element or compound. This process is attended by the liberation of heat, and, when it takes place rapidly, of light. The rusting of a given weight of iron is a slow oxidation, while the burning of the same in oxygen is a rapid oxidation. Only the latter produces light, while in both cases the same amount of heat is liberated.

By *combustion*, in a general sense, is meant the rapid union of the oxygen of the air with some other substance, as coal or phosphorus. In a wider sense, however, combustion may be defined as any chemical union of two substances attended by liberation of heat and light.

Crystalloids are substances which usually crystallize, and whose solutions are readily diffusible. *Example*—alum.

Colloids are substances which do not form crystals, and are not diffusible through porous membranes. *Example*—Albumin.

2.

THREE GENERAL ANESTHETICS.	CHEMICAL COMPOSITION (FORMULA).	CHEMICAL NAME.
1. Chloroform.	$CHCl_3$	Trichlormethane.
2. Ether.	$(C_2H_5)_2\ O$	Ethyl oxide.
3. Nitrous oxide.	N_2O	Nitrogen monoxide

Chloroform is a colorless liquid, volatile, with a strong, pleasant odor and a sweet taste; it is slightly soluble in water, but readily mixes with alcohol and ether; it is a good solvent for many substances which do not dissolve in water, such as phosphorus, fats, etc.

Ether is a colorless liquid with a sharp, burning taste and a peculiar odor; it is very volatile, very inflammable, and burns with a luminous flame. The vapor of ether, with air, forms a highly explosive mixture. It is a good solvent of several substances which do not dissolve in water and alcohol, such as fats and resins.

Nitrous oxide is a colorless, odorless gas, with a sweetish taste; it is soluble in water, also in alcohol; it is not combustible, but is a good supporter of combustion.

3. *Peroxide of hydrogen*, H_2O_2, is a colorless, syrupy liquid, heavier than water; it has a disagreeable metallic taste. It is a powerful oxidizing agent, also a bleacher and disinfectant. It is unstable, and it acts as a disinfectant and antiseptic by giving up free oxygen.

Potassium permanganate, $K_2Mn_2O_8$, is a crystalline solid, with a sweet and astringent taste, odorless, soluble in water. It is an oxidizing agent and disinfectant. It acts as a disinfectant and antiseptic by oxidizing the organic matter with which it comes in contact.

4. *Paris green* is, chemically, acetometarsenite of copper. The tests for its detection are the regular tests for arsenic and for copper.

Reinsch's test for arsenic is as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water,

dry on filter paper, but be careful not to rub off the deposit. Coil up the copper and put it into a clean, dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

5. In examining *normal* urine the following points are to be considered:

The quantity voided in twenty-four hours, its general appearance, color, odor, reaction, specific gravity, quantity of solids excreted, quantity of urea, uric acid, chlorides, sulphates, phosphates.

In *abnormal* urine, in addition to the above, examination should be made for albumin, sugar, excess of indican, acetone, blood, bile, pus, casts, epithelium, parasites, pathogenic bacteria, and foreign bodies.

6. *Tests for free hydrochloric acid in the gastric juice*:—The best is probably the Dimethylamido-azobenzol test; the reagent is used in 0.5 per cent. alcoholic solution, of which one or two drops are added to a like amount of the filtered gastric juice. If free HCl is present, the yellow solution turns red.

"*The presence of lactic acid* is detected by *Uffelmann's reagent*, which consists of a solution of Fe_2Cl_6 and phenol, diluted to an amethyst blue color, which is changed to yellow by lactic acid. In order to avoid error by the action of other substances which have a like action upon the reagent, 10 c.c. of the filtered gastric contents are agitated with ether, and the ethereal extract separated and agitated with the reagent; or, it may be evaporated, the residue dissolved in water, and the solution added to the reagent." (Witthaus' *Manual of Chemistry.*)

MATERIA MEDICA.

1. *Three drugs which will produce diaphoresis*:—Pilocarpus, Dover's powder, and Liquor ammonii acetatis.

2. The official preparations of arsenic, with their doses, are: Arseni trioxidum, gr. 1/30; Liquor acidi arsenosi, ♏vij; Arseni iodidum, gr. 1/20; Sodii arsenas, gr. 1/6, Sodii arsenas exsiccatus, gr. 1/20; Liquor potassii arsenitis, ♏vij; Liquor sodii arsenatis, ♏v; Liquor arseni et hydrargyri iodidi, ♏vij.

3. *Two galactagogues*:—Pilocarpus and the leaves of the castor oil plant, applied locally.

Two cholagogues:—Podophyllin and aloes.

Two sialagogues:—Pilocarpus and ipecac.

4.

	SOURCE.	DOSE.
Codeine.	Opium.	gr. 1/2.
Atropine.	Belladonna.	gr. 1/160.
Eserine.	Physostigma.	Of the sulphate, or salicylate, gr. 1/64

5. PHYSIOLOGICAL ANTAGONISTS:—Of *pilocarpine*: Atropine, strychnine, and morphine. Of *morphine*: Atropine, caffeine, cocaine, strychnine, and amyl nitrite. Of *phytolacca*: Alcohol, ether, opium, and digitalis.

6. *Dose* of: Santonin, gr. j; creosote, ♏ij; elaterium, gr. 1/6; sulphonal, gr. xv; podophyllum, gr. vijss; picrotoxin, gr. 1/90.

THERAPEUTICS.

1. Ergot stimulates and causes contraction of involuntary muscle fibers, hence it is a vasoconstrictor, hemostatic, and oxytocic. It is also a cardiac sedative; it raises the blood pressure, it increases peristalsis, and is an emmenagogue.

Indications for the therapeutic application:—To promote uterine contractions during third stage of labor; fibroids, menorrhagia, postpartum hemorrhage. Some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headaches, laxity of sphincters, of bladder or rectum, hemorrhoids, aneurysm, diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea.

2. *To determine the proper dosage for a child*: Let x = the age of a patient; then $\frac{x}{x+12}$ = the fraction of the adult dose which the patient should receive. Thus, a patient of four years old should receive $\frac{4}{4+12} = \frac{4}{16} = \frac{1}{4}$ of an adult dose.

3. SCOPARIUS:—*Active principle* is sparteine. *Dose*, of scoparius, is 3jss; of sparteine sulphate, is gr. 1/5. *Physiological action*: Diuretic; also diaphoretic and laxative; it strengthens the heart beat, slows the heart, raises arterial tension; it stimulates the vasomotor center to contract the abdominal vessels; the respiration is first quickened, then slowed and deepened.

4. *Ad libitum* means, at pleasure; *compositus*, compound; *fiat*, let it be made, or let there be made (singular); *chartula*, a little paper (for a powder); *macero*, I macerate; *misce*, mix; *pro re nata*, as occasion requires; *quantum sufficiat*, as much as may be sufficient; *ter in die*, three times a day.

5. *Cocaine* is an alkaloid derived from the Erythroxylon coca.

Symptoms of an overdose:—Pain and fulness in the head, pulse at first quick but later feeble and slow; extremities cold. The symptoms are not constant.

Treatment consists in the administration of ammonia or coffee; morphine, strychnine, chloroform, and ether have all been suggested; artificial respiration may be necessary. The safest plan is to treat whatever symptoms are present.

6. ℞ Ferri reducti, gr. xij.
Arseni trioxidi.
Strychninæ sulphatis āā, gr. 1/4.
Misce et fiat massa in pilulas no. xij dividenda.
Signa: Take one after each meal.

PATHOLOGY.

1. (*a*) *Method of staining the tubercle bacillus in the sputum*:—The sputum must be recent, free from particles of food or other foreign matter; select a cheesy looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin, red rods, while all other bacteria will appear blue.

3. A *physiological leucocytosis* is a leucocytosis which is found in certain physiological conditions; it is generally moderate and of brief duration. It is found in the newborn, after parturition, after exertion, after a cold bath or massage, during pregnancy, and during digestion.

A *pathological leucocytosis* is a leucocytosis which is found in certain pathological conditions; it is generally found in inflammatory, toxic, and infectious conditions. As a rule, the polynuclears are increased.

Of the diseases mentioned there is a leucocytosis present in: Appendicitis (sometimes only). It is absent in: Typhoid, malaria, and acute miliary tuberculosis.

6. In *pernicious anemia*:—"The color of the blood is often strikingly pale, though it may be dark, in spite of marked anemia. The specific gravity is reduced. The marked feature of the disease is pronounced oligocythemia. This progresses rapidly, and in ordinary cases the number of red corpuscles sinks to 1,000,000 or less per cu. mm.; at the same time, changes in size (microcytes and megalocytes) and in shape (poikilocytes) make their appearance and reach grades rarely attained in other diseases. Nucleated red corpuscles are always present in some number, and are usually abundant. The largest forms (megaloblasts) as a rule predominate, but in some cases the smaller forms are more abundant. Karyokinetic figures may be found in the nuclei. Polychromatophilia is generally present. The leucocytes may be decreased or normal in number; in the late stages leucocytosis is not uncommon, and it may become extreme. The larger mononuclear leucocytes are usually more abundant than in health, and myelocytes often occur in considerable numbers. In the terminal leucocytosis of pernicious anemia the lymphocytes often predominate."

In *chlorosis*:—"The blood is paler than normal and watery. The specific gravity decreases progressively, and the solid matter is deficient. Increased coagulability is sometimes observed. The number of red corpuscles may be normal even in well developed cases, but the proportion of hemoglobin sinks progressively. In prolonged cases the corpuscles become reduced in number, but the deficiency of hemoglobin continues to be excessive. Severe cases of chlorosis frequently show 3,000,000 or 2,000,000 red corpuscles per cu. mm. and 30 per cent. to 20 per cent. of hemoglobin. The red corpuscles may be little altered in appearance in the early stages; later, irregularities in size and shape are frequent, and nucleated red corpuscles (especially small forms) make their appearance. The latter sometimes occur in great numbers in crops (blood-crises). The leucocytes are usually normal in number and

kind; but in some cases myelocytes have been met with." (Stengel's *Pathology.*)

PRACTICE.

1. (*a*) An *endemic disease* is a disease which is found in a certain locality more or less constantly, as malaria and yellow fever in certain tropical regions.

(*b*) *Vocal fremitus* is the sense of vibration imparted by the voice of the patient to the hand of the physician palpating the chest.

It is *increased*: If the patient has a loud, low pitched, or harsh voice; when the lung is consolidated, as in pneumonia or tuberculosis.

It is *diminished*: If the patient has a feeble, high pitched voice; also in pleural effusions, pulmonary collapse, emphysema, obstruction of bronchus, edema of the lung.

(*c*) *Argyll-Robertson pupil* is a condition in which the pupil accommodates for distance but not for light. The condition is chiefly found in locomotor ataxia and paretic dementia.

(*d*) The *patella reflex* is nearly always *present* in health, and denotes a healthy condition of the entire reflex arc (tendon, afferent, or sensory nerve, posterior roots and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself). It is *absent* when there is a lesion which affects any part of this reflex arc, such as is the case in locomotor ataxia, poliomyelitis, Landry's paralysis, neuritis, in apoplexy just after the shock, and in epilepsy following the convulsion, etc. It is *exaggerated* in: Hemiplegia, lateral sclerosis, general paresis, transverse myelitis, injuries to the spinal cord, hysteria, neurasthenia, tetanus, and strychnine poisoning.

(*e*) In *Cheyne-Stokes respiration* the respirations gradually increase in volume and rapidity until they reach a climax, when they gradually subside, and finally cease for from ten to forty seconds, when the same cycle begins again.

"In the majority of instances it is associated with apoplexy (toward the end), chronic nephritis (uremia), tumor of the brain, tuberculous meningitis, or degeneration of the heart muscle. Less frequently it is observed as a result of cardiac valvular defects and consequent embolism, diabetes, and certain acute diseases, notably typhoid, pneumonia, pertussis, cerebrospinal fever, scarlet fever, and septicemic conditions." (Butler's *Diagnostics of Internal Medicine.*)

2. (*a*) The characteristic symptoms of Graves's disease are: (1) Tachycardia; (2) goitre; (3) exophthalmos, and (4) tremor.

(*b*)

CROUPOUS PNEUMONIA.	CATARRHAL PNEUMONIA.
Generally a primary disease.	Generally secondary (to bronchitis or an infectious disease).
Age has little influence.	Generally found in very young or very old.
Sudden onset.	Gradual onset.
Fever is high and regular.	Fever is not so high, and is irregular.
Ends by crisis between sixth and tenth day.	Ends by lysis, at no particular date.
Generally only one lung affected.	Generally both lungs affected.
The physical signs are distinct; and there is a large area of consolidation.	Physical signs indistinct; and the evidences of consolidation are indefinite.
Sputum is rusty.	Sputum is rather streaked with blood.

(*c*) *Gastric cancer* does not usually occur before forty years of age, is more common in males, pain is localized and constant, vomiting is copious and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; severe anemia and cachexia are also present.

Gastric ulcer is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents show an excess of free HCl.

3. (*a*) *In the acute nephritis accompanying or following scarlet fever*:—The patient should be kept in bed, kept quiet, and kept warm. Milk diet should be the rule; the milk can be diluted with limewater or Vichy. Salines, as potassium bitartrate or magnesium citrate or sulphate, and diaphoretics, as sweet spirit of niter, or pilocarpin, may be administered. Warm baths are helpful, and infusion of digitalis should be given.

(*b*) *Herpes zoster*:—The vesicles should be protected with collodion or zinc oxide; if the pain is very severe, morphine may be given; tonics and nutritious diet are indicated; strychnine or phosphide of zinc have been recommended.

(*c*) *Acute inflammatory articular rheumatism*:—The patient must lie in bed, between blankets, and in flannel; the affected joints and limbs must further be covered with warm flannel or cotton wool. Sodium salicylate or oil of wintergreen must be administered, and oil of gaultheria may also be applied locally to the affected parts. Acetate and citrate of potassium are also useful. For the pain, Dover's powder, or phenacetin, or morphine may be necessary. A cold bath is probably the best thing for the high fever. The diet should be liquid, and simple but nourishing.

4. *Spasmodic croup* generally comes on suddenly, at night. There is no appreciable fever, no previous malaise or sickness, and often the patient is asleep again by the time the physician arrives. There is frequently a thick, tenacious mucus, but neither Klebs-Loeffler bacilli nor streptococci are present. It is entirely a local disturbance.

Membranous croup is either laryngeal diphtheria or a streptococcus infection. In either case there is a prior stage of malaise, accompanied by chills, fever, and sore throat. The fever may become very high. A membrane forms, in which are found the Klebs-Loeffler bacillus or streptococci.

5. *Intestinal perforation in typhoid fever*:—Sometimes there is severe, sudden pain localized in the abdomen, and sometimes there is little or no pain. Marked tympanites, great weakness, collapse, anxious look, small, rapid pulse, and difficult breathing are present. The legs are apt to be drawn up, and nausea and vomiting may ensue. Hepatic and splenic dullness disappear, and leucocytosis may be present.

The *treatment* is surgical; laparotomy, with suture of the intestine, should be done as soon as possible. In the meantime opium (or preferably morphine) should be administered.

6. In *neuralgia* the pain is paroxysmal and intermittent; it is independent of the use of the nerve; it may vary in situation; painful points are not often present; the nerve trunk is not particularly tender, and a light pressure along the nerve trunk may cause as much pain as a heavy pressure; neuralgia only affects sensory nerves, and wasting and trophic disturbances only rarely occur.

In *neuritis* the pain is continuous, is always worse after use of the nerve, and does not vary in situation; painful points are present; the nerve trunk is tender, and the pain can be increased proportionately with pressure; it is not limited to sensory nerves, and trophic disturbances, wasting, and alterations in the electrical reactions are very apt to appear.

SURGERY.

1. In *acute synovitis* there are: Pain in the joint, which is worse at night and is increased by motion or pressure; the join is swollen, hot and tender; the swelling is fluctuating and elastic and conceals the outlines of the articular ends of the bones; the patient places the limb in the position of greatest ease; there is fever, which is proportionate to the size of the joint and the acuteness of the attack. *Treatment* consists in: Immobilization of the joint; firm bandaging and a splint; elevation of the limb and application of hot fomentations; application of leeches; massage or passive motion; later on, active movements, if possible; if adhesions exist they must be broken down, under anesthesia.

In *chronic synovitis* there are: Pain on movement or pressure, but not at other times; swelling and weakness of the joint; limitation of movement; fluctuation in the joint; atrophy of the muscles about the joint; later suppuration may occur. *Treatment* consists in: Rest; fixation of the joint; firm pressure on joint; blisters; massage; aspiration and drainage; the joint may be opened and hypertrophied synovial fringes removed and the joint washed out with sterilized water. The hot air apparatus is often of service.

3. The *symptoms of enlargement of the prostate* are: Frequent and difficult urination; the presence of residual urine; cystitis, pain and sense of fulness in the perineum.

Palliative treatment consists in: Regular catheterization, the administration of urinary antiseptics, bladder irrigation.

Radical treatment consists in: Prostatectomy, either suprapubic or perineal.

4. Nasopharyngeal growths and nasal affections all have a tendency to affect the mucous membrane of the nasopharynx, which is continuous with the middle ear through

the Eustachian tube. This mucous membrane becomes swollen, the Eustachian tube is obstructed, and consequently sufficient air is not admitted to the tympanum; the equilibrium of air is destroyed, the tympanum is retracted, the chain of ossicles is pressed inward, and sound conduction is interfered with. Inflammation of the middle ear, purulent or nonpurulent, may result.

6. The *indications for nerve suture* are: For repair of injury to nerve; in neuroplasty and nerve grafting or nerve implantation.

OBSTETRICS.

2. If the chin is presenting anteriorly, expectant treatment may suffice; but care must be taken to observe that the chin does not rotate backward. Spontaneous version may occur, and the presentation becomes a vertex one. Failing this, or as a means of favoring this, postural treatment, such as Walcher's position, has been recommended. If, in spite of this, engagement has not occurred, cephalic version is indicated. If this is not successful, podalic version should be tried. If, after all these manipulations the child is still alive and the head is engaged, symphyseotomy is indicated; if the child is dead, craniotomy should be performed.

4. The *dangers to be avoided in dilating the cervix* are: Infection, laceration of the cervix.

The *dangers to be avoided in curettage of the uterus* are: Sepsis, hemorrhage, perforation of the uterus, inflammation of uterus or aduexa, peritonitis, unintentional production of an abortion.

5. PERINEAL TEARS:—*Etiology*: Relative disproportion between size of the child and the perineal outlet; rapid labor; edema of the vulva; unfavorable head presentations (especially occipito posterior); large shoulders; poor perineal tissue.

Classification: (1) Slight; (2) when it reaches the margin of the anus; (3) when it reaches the splinchter ani and extends into the rectum.

Treatment: Repair, in all cases.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	July 13
Arizona*	Aneil Martin, Phoenix	Phoenix	July 5
Arkansas*	F. T. Murphy, Brinkley	Little Rock	July 13
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	Aug. 3
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	July 6
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	July 13
Delaware	J. H. Wilson, Dover	Dover	July 15
Dist. of Col'bia	Geo. C. Ober, Washington	Washington	July 13
Florida*	J. D. Fernandez, Jacksonville	Tallahassee	May 19
Georgia	E. R. Anthony, Griffin	Atlanta	April 30
Idaho*	W. F. Howard, Pocatello	Boise	Oct. —
Illinois	J. A. Egan, Springfield	Chicago	
Indiana	W. T. Gott, Crawfordsville	Indianapolis	May 2
Iowa	Louis A. Thomas, Des Moines	Des Moines	
Kansas	D. P. Cook, Clay Center	Kansas City	June 10
Kentucky	J. N. McCormick, Bowling Green	Louisville	April 27
Louisiana	P. A. LaRue, 211 Camp Street, New Orleans	New Orleans	May 20
Maine	Wm. J. Maybury, Saco	Augusta	July 1
Maryland	J. McP. Scott, Hagerstown	Baltimore	June 15
Massachusetts*	E. B. Harvey, State House, Boston	Boston	May 11
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June 8
Minnesota	W. S. Fullerton, St. Paul	St. Paul	June 1
Mississippi*	S. B. McLean, Jackson	Jackson	May 11
Missouri	J. A. B. Adcock, Warrensburg	Kansas City	May 4
Montana*	Wm. C. Riddell, Helena	Helena	Oct. 5
Nebraska	E. J. C. Ward, Oakland	Lincoln	May 5
Nevada	S. L. Lee, Carson City	Carson City	May 3
N. Hampshire	Henry C. Morrison, State Library, Concord	Concord	June 29
New Jersey	J. W. Bennett, Long Branch	Trenton	June 15
New Mexico	J. A. Massie, Santa Fe	Santa Fe	July 13
New York	C. F. Wheelock, Univ. of State of New York, Albany	New York Albany Syracuse Buffalo	May 18
N. Carolina	B. K. Hays, Oxford	Asheville	June 9
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	July 9
Ohio	Geo. H. Matson, Columbus	Columbus	June 8
Oklahoma*	P. P. Davis, Enid	Guthrie	July 6
Oregon*	B. E. Miller, Portland	Portland	July 6
Pennsylvania*	N. C. Schaeffer, Harrisburg	Philadelphia Pittsburg	June 22
Rhode Island*	G. T. Swarts, Providence	Providence	July 1
S. Carolina	H. H. Wyman, Aiken	Columbia	June 8
S. Dakota*	H. E. McNutt, Aberdeen	Watertown	July 14
Tennessee	T. J. Happel, Trenton	Memphis Nashville Knoxville	May —
Texas	C. B. Foscue, Waco	Cleburne	June 22
Utah	R. W. Fisher, Salt Lake City	Salt Lake City	July 5
Vermont	W. Scott Nay, Underhill	Burlington	July 13
Virginia	R. S. Martin, Stuart	Richmond	June 22
Washington*	K. Turner, Seattle	Seattle	July 6
W. Virginia	H. A. Barbee, Point Pleasant	Charleston	July 13
Wisconsin	J. V. Stevens, Jefferson	Madison	July 13
Wyoming	S. B. Miller, Laramie	Laramie	June 23

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Medical Items.

Civil Service Examination.—The following is the list of places where examinations are held, under the United States Civil Service Commission, for medical and other appointments by the national government. Application blanks for permission to come up for examination may be secured from the secretary of the board at the post office at any of the following named places, except where the letters "C. H." occur, which refer to the Custom House:

Alabama—Birmingham, Mobile (C. H.), Montgomery.

Arizona—Phœnix, Prescott, Tucson.

Arkansas—Fayetteville, Fort Smith, Little Rock, Texarkana.

California—Eureka, Fresno, Los Angeles, *Marysville, Sacramento, San Bernadino, San Francisco, San Jose, San Luis Obispo.

Colorado—Denver, Durango, Fort Collins, Grand Junction, Pueblo, Trinidad.

Connecticut—Hartford (C. H.), Middletown, New Haven.

District of Columbia—Washington.

Florida—Gainesville, Jacksonville, *Key West, Miami, Pensacola, *Tampa.

Georgia—*Athens, Atlanta, Augusta, Macon, Savannah, *Thomasville.

Hawaii—*Honolulu (C. H.).

Idaho—Boise, Moscow

Illinois—Cairo, Champaign, Chicago, Peoria, Quincy, Springfield.

Indiana—Bloomington, Evansville, Fort Wayne, Indianapolis, Lafayette.

Iowa—*Ames, Burlington, Des Moines, Dubuque, Fort Madison, Iowa City, *Mason City, Sioux City.

Kansas—Emporia, Fort Scott, Lawrence, Manhattan, Salina, Topeka, Wichita.

Kentucky—Lexington, Louisville, Paducah.

Louisiana—Baton Rouge, New Orleans (C. H.), Shreveport.

Maine—Bangor, Bath, Calais (C. H.), Houlton, Lewiston, Portland.

Maryland—Baltimore, Cumberland, Salisbury.

Massachusetts—Boston, Fall River, Fitchburg, Lawrence, Lowell, Pittsfield, Springfield, Worcester.

Michigan—Ann Arbor, Detroit, Grand Rapids, Manistee, *Marquette, Saginaw, Sault Ste. Marie.

Minnesota—Duluth, Mankato, St. Paul.

Mississippi—Greenville, *Meridian, Vicksburg.

Missouri—Columbia, Jefferson City, Kansas City, Kirksville, Springfield, St. Joseph, St. Louis (Old C. H.).

Montana—*Billings, *Bozeman, Butte, *Great Falls, Helena, Missoula.

Nebraska—Grand Island, Lincoln, Omaha.

Nevada—*Reno.

New Hampshire—Concord, Hanover, Keene, Manchester, Portsmouth.

New Mexico—Albuquerque, Las Vegas.

New York—Binghamton, Buffalo, Elmira, Ithaca, Jamestown, New York (C. H.), Ogdensburg (C. H.), Plattsburg (C. H.), Poughkeepsie, Rochester, Syracuse, Troy, Utica.

North Carolina—Asheville, Charlotte, *Durham, Goldsboro, Greensboro, Raleigh, Wilmington.

North Dakota—Bismarck, Fargo, *Grand Forks, *Minot, *Pembina (C. H.).

Ohio—Cincinnati, Cleveland (C. H.), Columbus, *Ironton, Toledo, Zanesville.

Oklahoma—Ardmore, Enid, Guthrie, McAlester, Muskogee, Oklahoma.

Oregon—Astoria (C. H.), Baker City, Eugene, Portland.

Pennsylvania—*Altoona, Harrisburg, Philadelphia, Pittsburg, *South Bethlehem, *Warren, Williamsport, Wilkes-Barre.

Porto Rico—*San Juan.

South Carolina—Charleston, Columbia, *Greenville.

South Dakota—Aberdeen, Deadwood, Sioux Falls, Watertown.

Tennessee—Bristol, Chattanooga, Knoxville, Memphis, Nashville.

Texas—Austin, *Brownsville (C. H.), Dallas, El Paso (C. H.), Houston, San Antonio, Waco.

Utah—*Logan, Salt Lake City.

Vermont—Burlington, Montpelier, Rutland, St. Johnsbury.

*Boards of Pension Examining Surgeons are located at all places mentioned in this list, except those marked thus *.

Virginia — *Charlottesville, *Lynchburg, Norfolk, Richmond, Roanoke, Staunton.

Washington—Bellingham, Port Townsend (C. H.), Pullman, Seattle, Spokane, Tacoma, Walla Walla.

West Virginia—Charleston, Fairmont, Parkersburg, Wheeling.

Wisconsin—Appleton, Ashland, Chippewa Falls, La Crosse, Madison, Marinette, Milwaukee, Wausau.

Wyoming—Cheyenne, *Laramie, Sheridan.

Tropical Medicine in the United States.—E. N. Tobey, writing in the *Journal of the American Medical Association* of April 3, 1909, pleads for the establishment of a course of tropical medicine in American medical schools. He reviews the objections: First, that the Government already has three schools; second, that the subject is of very little importance to general practitioners; third, that we have very little commerce with the tropics; fourth, that the subject is of vital importance only to Government agents abroad; fifth, that there is such a school in Manila, where tropical diseases may be studied; sixth, that the subject is better taught by the several departments whose fields it touches than by a special course; seventh, that there is but little clinical material for teaching purposes in such a place as Boston for instance. He answers these separately. The first objection was urged also in England, but in spite of this the London School of Tropical Medicine was established by the Government and has been utilized by American naval and military surgeons, as well as British officers who at first objected to it. Our officers evidently had to go abroad to obtain what they could not obtain here. The subject of tropical medicine is becoming annually more important on account of the return of discharged soldiers and sailors, missionaries, commercial agents, tourists, and others, who are as liable to return to the country as to the cities, and, in addition to this, the tropical types of malaria, dysentery, and even filariasis, have been known to originate within our own limits. Our commerce with the tropics is very great, amounting to hundreds of millions a year, and equal to more than half that of Great Britain, which controls one-fifth of the world. Our small army is constantly changing, and the treatment of the discharged soldiers has to be done at home. The southern part of the United States also is semitropical, and the treatment of the indigenous diseases must be done by civil practitioners at home. That there is a good laboratory and medical school at Manila does not meet the case. Manila is more than a month distant from us, and students should not be compelled to go so far. Tropical diseases are more frequent than is supposed in this country, and more will be reported when they are better recognized. At present only five medical schools here are giving special instruction in this department during term time, and much of this consists of a few optionally attended lectures. Is it not high time, Tobey asks, that we wake up and institute instruction in this important branch of medicine?

President Eliot on Football.—In the annual report of Harvard University for 1907-1908, the last to be written by President Eliot, this distinguished educator, himself, at the Psalmist's limit of endurable human life, still a notable example of physical as well as mental vigor, pays his parting compliments to football in the following words of no uncertain import (*Boston Medical and Surgical Journal*, April 1, 1909): "Although the game of football has been made more open and interesting by the new rules, and some of the foul play has been prevented by the neutral strip and other devices, the game still remains unfit for college uses, affords a demoralizing spectacle for the immense crowds which gather to witness the chief games, and still provides on a great scale the opportunity for that variety of gambling called betting. The betting evil is greatly increased by the practice of exhibiting the game in public halls in many American cities far remote from the scene of action. It is reasonable to expect that the barbarous stage of public opinion and college opinion concerning athletics, which in this country has been partly the result of inexperience in competitive sports and partly of the general predisposition to exaggeration in pleasures which characterizes Americans, will pass away before many years. Meantime the educated public may rejoice in the greater attention generally paid to school hygiene, preventive medicine, daily out-of-door exercise, and moderation in eating and drinking, with the great resulting improvement in the health and vigor of young men and women at the student age."

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending April 16, 1909:

		CASES.	DEATHS.
SMALLPOX—UNITED STATES.

A CATALYTIC THEORY OF INFECTION AND IMMUNITY.*

BY J. W. McLAUGHLIN, M.D.,

AUSTIN, TEXAS.

IT is now generally conceded that artificial or acquired immunity, resulting from an attack of the disease immunized against or from inoculations of the pathogenic agents of the disease, is a condition of the organism caused by specific antibodies in the serum or by immunizing tissue changes of the body.

It would seem evident, therefore, that a knowledge of the nature and action of pathogenic agents, of the synthesis and nature of specific antibodies, and of the character of the immunizing changes wrought in the tissues by pathogenic agents, is necessary to a lucid and rational knowledge of pathogenesis and immunization.

While many theories have been advanced from time to time, it must be admitted that we have no definite knowledge of the intimate nature of these subjects; and although toxins, in the broad sense of the term, are specific causes of disease, yet we know nothing of their chemical composition; if they possess a definite chemical structure it has not been defined nor has a revealing chemical test been described.

The failure of chemistry to determine the essential structure of toxins, together with the source and nature of the forms of energy, whose manifestations cause infectious diseases of many types, has led some observers to conclude that a toxin, in its essence, has no material existence—that it is a force, like magnetism, which may be more or less permanently attached to matter, but may be separated from matter without causing it injury. Some other observers regard the action of toxins as a vital phenomenon, whose nature lies beyond the limits which circumscribe science. Oppenheimer, in "Ferments and Their Action," says "Of the ways and means by which the *peculiar forms of energy* of ferments develop their activity we have not the slightest trustworthy idea." And that which he has said of ferments is equally true of toxins.

It seems, therefore, in the present state of knowledge, that the nature and action of pathogenic agents, the origin and nature of specific antibodies, and the character of immunizing changes that toxins produce in the tissues of the body in the process of its infection and immunization are not sufficiently definite to afford a sound basis on which to construct a rational and lucid theory of pathogenesis and immunization; and yet no subject, surely no medical subject, has received within the present decade greater consideration or more scientific investigation by persons equipped for the work. It seems not too much to expect that a physical problem, however abstruse, should yield a knowledge of its mysteries to investigations of this thoroughness and character when made by those properly equipped provided a knowledge is had of the principles of matter and energy that underlie and control the phenomena of the subject. Are the failures which have resulted due to insufficiency of our knowledge of the underlying principles?

In seeking the causes of chemical action we naturally go to chemistry for information, but our search finds nothing more definite than vague terms like "chemical forces," "chemical affinity" and the "internal forces of matter"—all of which are unknown. Chemistry is more occupied in describing how chemical changes occur, than why they occur. Mellor,[1] in the introduction to "Chemical Statics and Dynamics," says: "And this is the purpose of chemical science, to describe in the simplest possible manner the phenomena associated with matter in the act of changing. The word 'describe' has been selected with deliberation. The more important advances of modern sciences have been achieved by keeping the descriptive not the causal relations of phenomena constantly in view. In consequence 'why' is rapidly disappearing from our vocabulary. We do not inquire why oxygen unites with hydrogen, but we do seek for all the conditions under which the transformation is possible. The search for the first cause has been relinquished. 'How' is the direct object of attack." Our search for the fundamental principles of matter and energy must then be found, if at all, elsewhere than in chemistry.

Many years ago when trying to learn the nature of therapeutic energy, and later, in seeking the nature of pathogenesis and immunization, I was forced to conclude that the "internal forces of matter," frequently mentioned in current literature but not explained, consist in something more than heat energy developed by molecules in their movements of translation and mutual collisions; that standing back of molecules, and independent of the heat energy and its transformations, there are unknown forces—properties of matter, which determine chemical combinations. I was, therefore, led to seek an explanation of the internal forces of matter in a mental analysis of matter itself, and its motions, along the following lines of inquiry:

"Theoretical Chemistry," says Julius Thompson[2] in the introduction to "Thermo-Chemical Investigations," "is based upon the molecular theory, according to which all matter is made up of molecules, and these molecules of atoms. The physical state of bodies depends upon the arrangement and motions of the molecules; the other physical and chemical properties depend upon the kind and number of atoms in the molecules, upon their arrangement and relative motions." When examined more in detail, the propositions contained in the statement

*Read before the Texas Academy of Science, March 10, 1909.

quoted will show that atoms are chemical units which, according to the teachings of modern science, are made up of infinitely smaller energetic bodies whose dimensions do not exceed the ten-thousandth part of a hydrogen molecule.

They are not quiescent bodies, on the contrary, are in constant vibrations; each kind of atom moving in periods which distinguish it from other kinds of atoms. The science of Spectroscopy is based upon this fact. Professor Clerk Maxwell, in a contribution to the Encyclopedia Britannica, article, "Atoms," suggests that "Atoms exist of various kinds having their various periods of vibration either identical, or so nearly identical that our spectroscopes cannot distinguish them." "The same kind of atom, say of hydrogen, has the same set of periods of vibration, whether we procure the hydrogen from water, from coal, or from meteoric iron." Lord Kelvin, in his vortex hypothesis, not only attributes to each kind of atom distinctive motions, but holds that the motion of the atom may be the sole character which distinguishes it from other atoms.

A molecule is the smallest division of matter that retains the characteristic qualities and properties of the substance. Hence there are as many kinds of molecules as there are kinds of substances. Molecules are made up of atoms, usually of different kinds, vibrating in characteristic periods, and grouped in space (stereochemical configuration) in many ways. "The physical state of bodies depends upon the arrangement and motions of the molecules: the other physical and chemical properties depend upon the kind and number of atoms in the molecule, upon their arrangement and relative motion." But the picture is not yet complete—there remains to be added to molecular structure, that of molecular motions. The molecules of a mass are in active movements of translation—moving at random, or otherwise, hither and thither, colliding, perhaps breaking up into "ions," or atoms, which may recombine in various ways, perhaps again to separate and recombine and continue to separate and combine until an equilibrium of the reacting forces is finally reached in stable end products.

When to our knowledge of molecular structure is added that of molecular energy we will have before us the complete molecule as it is described in our text-books. But taking up the study at this point, where it seems to have been abandoned, two new features will be added, and when this is done it will become apparent that molecular energy is derived from molecular structure, and that changes of matter in chemical reactions result from the interaction of atomic and molecular forces in securing equilibrium in end products. The first feature to be added is the presence of the universal ether, surrounding atoms in the molecules, and accurately reproducing their vibrations as ether waves. The second feature is an adjustment of conflicting ether waves in the molecules by "interference" into waves of energy, whose periods coincide in crest and trough.

The mutual neutralization of the waves of light as seen in Newton's rings when the crest of one wave falls upon the trough of another, or the neutralization of two sound waves, one by the other, gives an illustration of this beautiful principle of nature, which Sir John Herschell says, "For beauty, simplicity and wide extent of application, has hardly its equal in the whole circle of science." Under the operations of this principle the ether waves produced in the molecules by vibrating atoms will be adjusted, and will coincide crest and trough. When this is accomplished, the sum of their impacts, recurring millions of times in a second, will make them waves of energy. Further than this, the set of adjusted waves will accurately represent and vary with the chemical and physical structure of the molecule; that is, with the number and kind of atoms it contains, stereochemical configuration or the arrangement of the atoms in space, and the operations of the principle of interference. The energy of a molecule is, therefore, *an exact reflex of its chemical and physical structure.*

The opinion that molecules are drawn together by chemical affinities is no longer held, and the teaching of modern chemistry is that collisions between molecules in their motions of translation are matters of accident, and that "internal forces of matter" alone determine what, if any, chemical union will take place between colliding molecules. This view seems in perfect agreement with the concept that the internal forces of matter arise from atomic and molecular ether waves, and when collisions bring molecules within the mutual spheres of their wave action, the principle of interference will determine what unions will occur.

But let us see under what conditions molecular energy as described becomes catalytic energy. The ether waves which surround all molecules and represent their chemical and physical structures are waves of potential energy, which becomes transformed into waves of dynamic energy when brought in contact with waves of other molecules they can influence or be influenced by. Molecular waves are equalized—neutralized—in stable compounds but this general rule cannot apply to the waves of the molecules which occupy the surface of the mass, since there are no opposing molecules to furnish opposing waves. Waves of the surface of a mass are, therefore, waves of potential energy, the form of which varies with molecular structure, and the intensity of which is directly proportional to extent of surface, and inversely proportional to size of mass. These waves are catalytic waves, and any substance usually a colloid—whose surface is greatly exaggerated in proportion to its mass—is a catalyst. Hence *a catalyst is not a definite chemical substance but a substance possessing a definite physical structure.*

I feel quite sure that whatever opinion of value this theory as a whole may receive will be determined largely by the estimate placed upon that part of the theory which attempts to explain the nature and forms of energy of catalytic agents. I am therefore sure of your indulgence while I seek to strengthen this part of my subject.

The following-named properties of a catalyst are designated "Articles of Faith," by Mellor, ibid because they are universally accepted as characteristic phenomena of catalysis; and when the unknown source of these phenomena is thoughtfully considered in its probable relation to the catalyst I feel almost sure you will see, as I do, that a catalyst constructed on the lines described will furnish a lucid and rational explanation of the why and wherefore of these "articles of faith."

The "articles of faith" described by Mellor are as follows: "A catalyst has the same chemical composition at the beginning as at the end of a reaction." "A small quantity of a catalytic agent is sufficient to effect the transformation of an indefinitely large quantity of the reacting substance."

"The phenomenon of catalysis is universal." "There is probably no kind of chemical reaction," says Ostwald, "which cannot be influenced catalytically, and there is no substance, element, or compound which cannot act as a catalyser." "The activity of a catalytic agent depends on its physical condition . . . as a general rule the finer the state of division the greater will be its chemical activity." "The function of a catalytic agent is to direct the transformation along one path in preference to another."

Bredig and von Bermak have demonstrated that ultramicroscopic pieces of platinum, torn loose by the electric current from platinum terminals immersed in distilled water, possess in a marked degree the properties of a ferment; and since the only difference between these ultramicroscopic pieces of the metal and larger pieces of the metal is the proportional relation of surface to mass, the acquirement of ferment properties by the ultramicroscopic pieces must be due to an enormously exaggerated surface in proportion to mass. Hence, conferring ferment action upon some of the metals by greatly increasing molecular surface in proportion to mass seems to indicate that ferment and catalytic energy are alike in their nature and origin; and that the Bredig phenomenon justifies placing ferments as catalytic agents—a classification that is everywhere accepted.

Are toxins entitled to be classified with ferments as catalytic agents? The statement has already been made that nothing is known of the essential composition of a toxin. If it has a definite chemical structure it has not been made known; and the nature and origin of the forms of energy, by the use of which pathogenic agents bring about the many types of infectious diseases, are absolutely unknown. So, when the striking similarity these features bear to those of ferments is considered in connection with other facts equally analogous which characterize ferments and toxins, the question whether toxins and pathogens shall be classed as catalytic agents may be answered in the affirmative.

Among the features common to ferment and pathogenic reactions the following are the most conspicuous: A small quantity of a catalytic agent is able to transform an indefinitely large quantity of the reacting substance. For example: One part of rennet—a ferment—can transform at least 4,000,000 parts of caseine (Oppenheimer); one part of invertase—a ferment—can transform 200,000 parts of cane sugar (O'Sullivan and Thompson); one unit of diphtheria toxin, it is claimed, can produce ten thousand units of anti-toxin, and this quantity may be largely increased by frequent bleedings of the horse. The enormous increase of smallpox virus, a toxic agent which develops in the pustules covering the body, affords another illustration where a small quantity of a pathogenic agent transforms an enormous quantity of the reacting substance.

Specificity of action and the production of specific antibodies are features which definitely characterize catalytic reactions whether the catalyst be a pathogen, toxin, ferment, or enzyme. The relation a specific pathogenic agent bears to the type of the disease it may produce, and the relation which the specific antibody produced in the serum by the infectious agent, bears to this agent, are examples of specific relations in pathogenic reactions. The structure relation a species of ferment bears to its substrate, and the relation the antibody produced in the reaction bears to the ferment are examples of specific relations in fermentation.

A concrete example of the specific relation in structure which a ferment bears to its substrate is furnished by the behavior of a ferment, say emulsin, toward two series of glucosides, say the α-methyl and the β-methyl series.[3] The glucosides of both series are chemical isomerides—that is, the molecules of the two series contain the same kind and the same number of atoms, yet emulsin will ferment one of the glucosides but does not affect the glucosides of the other series. Now, since the glucosides of the two series are identical in chemical make-up, the selective action of emulsin is not based on chemical affinity. And since the glucosides of the two series differ in stereochemical configuration—that is, in placing or grouping in space of the atoms in the molecules, it is claimed the selective action of the ferment is due to this difference in physical structure. And since, as shown, a form of molecular energy is an exact expression of the chemical and physical structure of the molecule, and transformation of matter requires an expenditure of energy, it becomes clearly apparent that the specific selective action of a ferment for the substrate is coincident in crest and trough of the waves periods of the two substances—ferment and substrate.

The development of a specific antibody in the serum of a normal animal, produced by introducing into the tissues (inoculating) a specific pathogen, toxin, ferment, enzyme, or an alien proteid, is a phenomenon whose truth is an accepted fact, but whose cause is not known. But since antibodies have not been produced in the serum of an animal by inoculations of ptomains, alkaloids, or any substance whose chemical composition is known,[4] may we not conclude that the transformation is not a simple chemical reaction in which the directing forces come from the changing substances, but is a catalytic reaction, in which the forces directing the transformation come mainly from the catalyst; a reaction in which a pathogen, toxin, enzyme, or alien proteid is the catalyst and a specific antibody is the end product.

A theory of specific antibodies which includes these features is in harmony with the action of a catalyst described, and will receive an intelligible interpretation when considered in connection with the "article of faith" that "The function of a catalyst is to direct the transformation along one path in preference to another."

Permit me to elucidate the transformation by presenting its supposed features from an energy point of view. The energy waves which direct the transformation in a chemical reaction come from the changing substances, and are again fixed—equalized in the final products; but the energy waves of a catalyst, which direct the transformation in a catalytic reaction, do not come from the changing substances, and are not wholly fixed—equalized—in the end products; a part remain waves of potential energy of the end products. The why and the wherefore of this may be seen when a catalytic reaction is observed from an energy viewpoint, and in the light of our concept of a catalyst.

The molecular waves of a catalyst are waves of potential energy which are transformed into waves of dynamic energy when brought in contact with molecular waves of other substances they can influence—increase, retard, or neutralize. When dissociation of a substrate by a catalyst has taken place, the dissociated elements will seek to recombine into end products, but are handicapped by the energy waves of the catalyst. It seems evident that,

of the combinations possible for the elements to enter into, none can take place under the timely impacts of the energy waves of the catalyzer whose wave periods coincide with these in crest and trough, since coincidence must cause dissociation. The less the wave periods of a possible end-product of the reaction coincide crest and trough with the catalytic agent, the less difficulty will be met in effecting a combination of the dissociated elements, and when the wave trough of the end-product corresponds with the wave crest of the catalyst, the chemical line of least resistance will have been reached. But since an end product of the dissociated elements of a catalytic reaction—a substance that has combined the elements along a line of chemical union of least resistance—that is a line of chemical union in which the energy waves of the catalytic agent and final product mutually neutralize each other—it becomes clearly apparent that the molecules of the end product are specific antibodies to the molecules of the catalyst.

If this argument is sound; and it is conceded that definite specific relations which exist between a pathogen and the disease it may cause are identical in nature to those that exist between a ferment and the substrate it can transform, it will necessarily follow that specific antibodies to a pathogenic agent are end products of a reaction in which a pathogen or toxin plays the rôle of catalyst. But this conclusion cannot be fully established until a substrate or substrates capable of satisfying the requirements of a multiplicity of species of pathogenic microorganisms, are found in the body tissues of the organism.

The fact that a substrate is not vulnerable to a pathogen or ferment except it coincides with it in crest and trough, requires that the body shall contain a vulnerable substrate for each species of microorganism to which it is susceptible, or that it contain a substance composed of molecular groups in great variety, all of which are alike in chemical compositions but differ, one group from another group, in stereochemical configuration—that is, in the relations which the atoms in a molecule are placed in space.

There is much evidence that the tissue juice of the body—its serum—is composed largely of free albumin molecules of many chemical isomerides, which possess in common the chemical structure of the albumin, but differ greatly in physical structure and, therefore, meet the required demands.

This conception of the structure of the free albumins of the tissue juices throws light on unknown problems of metabolism, as may be seen when we consider that the albumins compose the great bulk of the tissue of the body, and the various structures, as the many kinds of glands, the membranes, the muscle, the epithelium, the vessels, the brain and nerve, the skin, bones, and hair structures, all receive nourishment of the particular kind they require for the repair of waste and for functional uses from this common supply—the albumins of the tissue juices. It seems almost inconceivable that a homogeneous substance such as albumin can supply the particular forms of nourishment to structures so heterogeneous. We are, therefore, almost driven into the belief that the free albumin molecules of these fluids comprise many chemical isomerides.

But when it is established that the albumins contain groups of chemical isomerides in great variety the problem of tissue metabolism will be greatly simplified, since the physical structure of molecules which are chemically identical is sufficient to determine their vulnerability to transformation. This has been shown in the instance of emulsin and the glucosides. Hence, when it is known that tissue metabolism is a process of catalysis, the principle of interference will enable the molecules of each particular tissue to select from the albumins the particular groups of molecules they can utilize. And for the same reason, the albumins will furnish substrates for the many species of pathogenic microorganisms to which man is susceptible.

Experimental investigations, not long since carried on, conclusively show that the blood of an animal is characteristic of the species to which it belongs. For illustration, a proteid of one species of animal when inoculated into an animal of another species will develop a reaction in the serum of the animal treated, and a specific antibody will appear in its serum. This antibody (precipitin) is specific; for example, the albumin of a hen's egg, the blood of man, the kidney, or any other form of protein, say from a rabbit, inoculated into the tissues of an animal of another species will cause the development of a specific "precipitin" in the serum of the animal treated. And when the albumin of a hen's egg is added to the serum of the rabbit treated, the "precipitin" will combine with this albumin but will not combine with any form of albumin obtained from a different species. So with the blood of man or other form of protein inoculated into an alien animal, it will combine with a "precipitin" developed by it in the serum of this animal but with that of no other precipitin. The reaction is definitely specific since it will combine with the same kind of protein, from the same species, and with no other.

The strong resemblance which the phenomena of the reaction described bears to those of a catalytic reaction, forcibly suggests an identity of cause, and therefore indicates that the feature of specificity is due, in this case as it is in that of catalysis, to a corresponding relation in crest and trough of the energy waves of the proteid and substrate. This brings us back again, and furnishes additional evidence to that already mentioned, to the concept that the albumins contain many groups of chemical isomerides.

An acceptance of the propositions discussed leads unerringly to the conclusion that pathogenesis is a catalytic reaction in which a pathogen or toxin is the catalyst, a group of albumin molecules is the substrate, and a specific antibody is the end-product.

In this process the albumin molecules of the substrate are dissociated and transformed into a toxalbumin, and this *is the essential cause of the disease produced, the type of which is determined by the character of the toxalbumin, and the character of the toxalbumin is determined by the species of pathogen and the vulnerable substrate engaged in the reaction.*

When it is concluded that pathogenesis depends on the coaction of two factors—the pathogenic agent and its substrate, the absence of either of these will result in immunity. When, for example, there is a natural absence of the albumin molecules which comprise a substrate, the organism—say of man—will be naturally immune to the pathogenic agent of this substrate. And when a substrate has been destroyed by the pathogenic agent, either in a prior attack of the disease or by inoculations of this agent, the organism will be made artificially immune against further infection by the pathogenic agent. This agent is then non-pathogenic to the

organism, which may remain harmlessly in the tissues of the immune body.

The character of the immunizing changes wrought in the tissues by a pathogenic agent is now made clear, but it may be asked—what rôle do specific antibodies play in this scheme of immunity? It has been explained why an antibody is an end-product of a catalytic reaction, especially when the reacting bodies are colloids and the state of the end-product is molecular, and why the specific relation of antibody and catalyst is a relation of wave energy of opposite sign, in which the waves of the antibody neutralize the waves of the catalyst.

It may be seen, therefore, that an antibody—say an antigen to a pathogen, or an antitoxin to a toxin, combines with, neutralizes, and thus makes harmless, the pathogenic agent. But since such combinations are bodies which are foreign to the organism they are soon disposed of, and the immunity produced by them is transient in character. On the other hand; immunity produced by destruction of the substrate is lasting, and will remain until the substrate is restored.

CEREBRAL LOBULES.

ANATOMY OF THE HOLMES NAUTILUS.

By WALLACE WOOD, M.D.,

NEW YORK.

AUTHOR OF "CEREBRAL SCIENCE" AND "A NEW METHOD IN BRAIN STUDY."

In the anatomy of the brain there is a science of fissures, a science of gyri, and a science of lobules. The lobules are centers of mind force, centers of feeling and imprint, æsthesic and mnemonic if extended, pathic and typic if intense.

In an article published in the Medical Record of June 2, 1906, I sought to prove that the eight marginal lobules were the heads of cerebral segments and that the human cerebrum was segmented like an annelid or a nautilus or like a vertebral column. This view has since received confirmation both from embryology and histology.

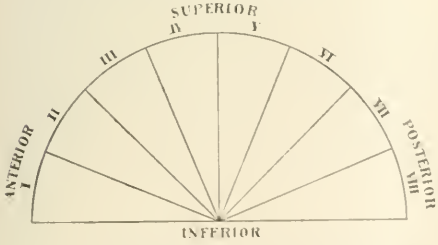

Fig. 1.—Brain schema making out the eight cerebral segments

Cerebral localization properly deals with centers. If the cerebral segments are one by one examined in detail it will be found that they lend themselves wonderfully well to the theory of sensory and motory centers and that these sensory and motory centers are definitely formed eminences or lobules, each with a function, and that they tend to be regular in order and to lie along definite lines. In this view a simple and practical method of mapping out the brain and reading these psychological centers or mind eminences is as follows:

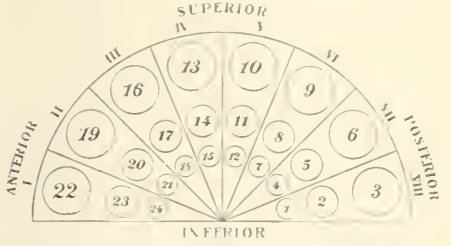

Fig. 2.—Schema for indicating the anatomy of the cerebral lobules and localizing the functional centers; 1, the under temporal lobule; 2, the tempero-occipital lobule; 3, the under occipital lobe; 4, the superior temporal lobule; 5, the angular gyrus; 6, the occipital lobe; 7, 8, 9, parts of the parietal segment; Segment V—10, 11, 12, the three lobules of the grand motor; 13, 14, 15, foot of the first, second and third frontal gyri, respectively; 16, 17, 18, heads of the three frontal gyri; 19, 20, 21, prefrontal; 22, 23, 24, subfrontal

On a sheet of paper mark out a half circle, or, better, a half oval. This represents the side of a head or cerebrum.

At the sides write the words "anterior," "posterior," "superior," "inferior," and divide the half oval into eight segments. Number the segments I to VIII, beginning at the front. In each of these cerebral segments draw three circles as indicating the mind centers, globules of feeling, memory, thought. These may be enumerated from posterior to anterior as follows: 1. The under temporal lobule; 2, the tempero-occipital lobule; and, 3, the under occipital lobe.

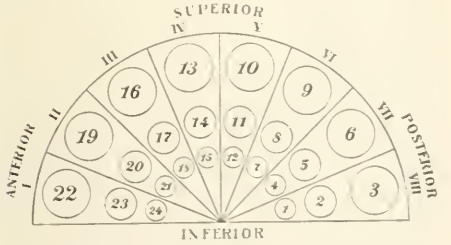

Fig. 3.—Schema for the localization of cerebral lobules as centers of mental force: VIII—1, 2, 3, Taste, Striving, Attachment; VII—4, 5, 6, Ear, "Memory," Eye; VI—7, 8, 9, Temper? Conscience? Personality; V—10, 11, 12, Power, Energy, Grasp; IV—13, 14 15 Gesture, Writing, Speech; III—16, 17, 18, Good Will, Imagination, Linguistics; II—19, 20, 21, Contemplation, Thought, Concentration; I—22, 23, 24, Calculation, Experiment, Observation.

The segment next will include the superior temporal lobule, the angular gyrus and the occipital lobe.

Your next segment higher covers the supramarginal lobule, the parietal lobule, and the quadrate.

You then arrive at the Rolando region, or grand central motor, with its superior, middle and inferior lobules. In front of the segment of motion lies the segment of expression. This consists of the foot or pedal of the first frontal gyrus, the foot or pedal of the second frontal gyrus, and the foot or pedal of the third frontal gyrus.

Anterior to this is another segment of three lobules. There are the head or cap of the first frontal gyrus, the head or cap of the second frontal gyrus, and the head or cap of the third frontal gyrus

In the prefrontal segment, finally, we see the racinc of the first frontal gyrus, the racine of the second frontal gyrus, the racine of the third frontal gyrus, and the gyrus rectus.

What are the functions of these twenty or more brain centers, these twenty-four cerebral emi-

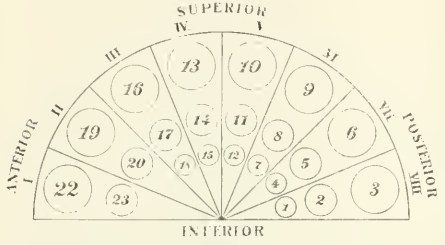

FIG. 4.—Schema for cerebral localization junctions of lobules indicated in Greek, as follows: VIII—1, 2, 3, Geustic, Athletic, Genetic; VII—4, 5, 6, Acoustic, Biblic, Optic; VI—7, 8, 9, Thymic, Stereognostic, Autopathic; V—10, 11, 12, Autocratic, Energetic, Philokerdic; IV—13, 14, 15, Pantomimic, Graphic, Phonetic; III—16, 17, 18, Prothymic, Phantasic, Philologic; II—19, 20, Philosophic, Theoretic; I—22, 23, Epistemic, Bouletic.

nences? Part of these are known, part are well known, part are guessed, suggested or surmised, and part are unknown.

Let us see. The under temporal lobe is the criterion of smell or taste, the temperooccipital lobe is a great vital association center. Is it the seat of courage and the will to live?

The under occipital lobe—is it the anthemion? is it the affectional center?

The superior temporal gyrus is the hearing center; the occipital lobe is the sight center; the angular gyrus is the center for written words; it is the cerebral book-worm?

The supramarginal lobule, is it the center that lays the ears back when the animal bites? Is it the lobule of animosity? Is it irritability?

The parietal and quadrate above this, form a great posterior association or cogitation center marked "stereognostic." This is the lobe of the knowledge of the hard and cold world and necessarily of the contra of that hard, cold world, namely, the self. The region is hydra-headed or many headed indeed. It is the lobe of "self and the world," self against the world.

The three lobules of the motor segment or sensory motor segment are power of the foot, power of the hand, power of the jaw.

There are the oppressor, the worker, and the gainer; or, again, they are the ruler, the fighter, and the possessor.

The lobules of the next segment are the feet of the first, second, and third frontal gyri, and these functions are gesture, writing, and motor speech.

The next, the true frontal segment, is forehead and eyes, and also covers the head of the third frontal gyrus.

From the study of the forehead of good horses and good cows in which the superior lobule is full, one might call it the lobule of faithful service. It might have a hundred other names. In the sheep it means commonality or sociability. Is it larger in women than men? In the dog it is good will. Below it is the lobule of frontal vision which can be nothing else than the eye of imagination, and below this the part of the talking gyrus, which can be nothing else than philologic or linguistic.

There remains the prefrontal region in which are believed to reside the most advanced and most concentrated powers of thought, science, and control.

By means of a little practice with the diagrams here presented the student of the science of man may read with facility and felicity any brain or the profile of any living head.

PERSONAL OBSERVATIONS UPON URETERAL CALCULI.*

BY ALEXIS V. MOSCHCOWITZ, M.D.,

NEW YORK.

VISITING SURGEON MOUNT MORIAH HOSPITAL; ADJUNCT ATTENDING SURGEON MOUNT SINAI HOSPITAL.

URETERAL calculus is a disease that has been added to the domain of surgery, practically only since the discovery of the Roentgen rays. The number of reported operations for this lesion previous to this period are very few, probably not more than half a dozen. The clinical manifestations of ureteral calculi were included under those of renal calculus; and it is interesting to observe that since the use of the *x*-rays, a large majority of clinically diagnosed renal calculi are really of ureteral situation. Although the number of reported cases of ureteral calculi have thus been vastly augmented in recent years, they are nevertheless anything but common incidences. I have been peculiarly fortunate in having seen an unusual number, and my experiences have been highly instructive. It is for this reason, as well as for its comparatively unappreciated importance that I have selected the subject of ureteral calculus as the theme for my discourse to you.

Surgical Anatomy.—The surgical anatomy of the ureter has been amply and beautifully described by Byron Robinson (*Annals of Surgery*. Vol. 36, page 850), and an excellent monograph upon this subject has appeared by Zondek ("Zur Chirurgie der Ureteren," Aug. Hirschwald, Berlin, 1905). I wish to recall merely one point in the anatomy of this organ that is of surgical importance.

In textbooks the ureter is described as being narrowed at three anatomical points, namely (1) at or about the junction of the ureter and the pelvis of the kidney; (2) at the vesical end, and (3) at the point where the ureter crosses the common iliac artery. Between these points the ureter is composed of spindle-shaped segments.

These points of constriction are of importance because they are the sites of predilection for the impaction of calculi. In addition to these three points, however, I am able to say, from my own experience, that there is probably a fourth point, hitherto to my knowledge, not sufficiently appreciated. In a considerable number of my cases, in fact in sixteen out of eighteen, I have found a calculus impacted at a point between the vesical end of the ureter and the point where it crosses the common iliac artery, perhaps a trifle nearer to the former. I have found this point of constriction of the ureter not to be due to any internal narrowing, but to a dense, sharp, fascial band (sometimes containing a small blood vessel) which passes horizontally inward from the lateral pelvic wall to the median line. It has been my experience that it is always necessary to divide this band of fascia, in order to mobilize the lowermost segment of the ureter. The constant presence of this band leads me to the belief that the impac-

*Read by invitation at a meeting of the Hartford (Conn.) Medical Society, December 28, 1908.

tion of calculi in this portion of the ureter is not wholly due to the slight change in direction which the ureter takes in this part of its course. As it occurs in the male and female sex as well, the broad ligament and uterine artery cannot be looked upon as factors in its production.

Symptomatology and Physical Signs.—The classical symptoms and signs of calculus in the upper uninary tract are well known and do not require repetition. I wish merely to emphasize a few points that I have found of service in diagnouis.

The symptoms of urinary calculus, as of cholelithiasis, depend largely upon whether the calculus is in the quiescent or migratory stage, and furthermore upon the presence or absence of infection. If the calculus is quiescent, the only symptoms and signs are a constant and fixed pain, with a point of tenderness, either in the back, in the costovertebral angle, or the front of the lateral abdominal wall, and the presence of blood in the urine in microscopic quantities. In the later stages we have added to these symptoms those of infection. I regard the presence of microscopic blood in the urine as a very important symptom of either renal or ureteral quiescent calculus; in fact, I cannot recall a case of renal or ureteral calculus in which red blood cells were not found on careful microscopical examination. If, on the other hand, the calculus is migrating, there arise all the classical symptoms of renal colic, and a greatly augmented hematuria. In the history of most cases, we find that the symptoms of the quiescent and migrating calculus alternate, but as a rule we also find that the periods of remission have a tendency to become shorter and shorter.

It is not commonly appreciated that a calculus in the ureter may give rise to symptoms referable to the bladder. This, however, occurs only when the calculus is situated very near the vesical end of the ureter. Even long before the calculus has become extruded partly or wholly into the bladder, the patient begins to complain of symptoms of vesical irritation, increased frequency of urination, tenesmus, etc. The appreciation of this point is of importance, because it not infrequently happens that these symptoms are mistaken as evidences that the calculus has passed into the bladder. I do not refer to the occasionally present, slightly increased frequency of urination, which is so often due to infection and an accompanying cystitis; but to a distinct vesical tenesmus, which, as already stated, is caused by a ureteral calculus approaching the bladder.

None of the symptoms that I have outlined above furnish us conclusive evidence in regard to either the presence or site of the impacted calculus. It might be thought that the determination of a point or points of tenderness upon the abdominal wall would indicate the site of the calculus. I have found, however, that this sign is often deceptive. It is a peculiar physiological phenomenon that when a ureter is the seat of a calculus, the tenderness is not limited to the site of the calculus, but to the entire extent of the ureter. I believe this generalized tenderness is due to a greater or less degree of associated inflammation of the mucous membrane, and to tension caused by a retardation in the urinary flow. I need hardly say that palpation furnishes us accurate knowledge of the site of the calculus, when it is in one region, namely, at the vesical end of the ureter in the female, when it can often be palpated *per vaginam*.

Cystoscopic inspection of the bladder is also of comparatively limited value in the diagnosis. Of course, if the calculus projects from the vesical end of the ureter, it will be readily visible; and if we note bloody urine passing from one or other ureter, we can be sure of the side upon which the calculus is present. In addition to this, if the calculus is in the lowermost part of the ureter, the ureteral orifice, instead of being slit-shaped, presents the so-called "golf hole" appearance.

The cystoscopic passing of the ureteral catheter affords us better knowledge than the previous two methods of physical examination. In the first place, it will find and indicate the point of an obstruction in the ureter; and in the second place, if the catheter is tipped with wax, the presence of scratch marks will furnish strong presumptive evidence that this obstruction is a calculus; but care must be taken to exclude accidental scratch marks caused by the cystoscope itself. I may say in passing that occasionally a ureteral catheter may pass easily, even if a calculus is present, especially if the calculus is small or of irregular shape; this occurred in one of my cases. After all, the most important and pathognomonic method of examination is the *x*-ray.

I regard an *x*-ray examination an absolute necessity in every case of ureteral calculus, and for the following reasons: 1. It indicates the presence or absence of a calculus. 2. It shows the situation of the calculus; this is important, because it indicates almost with mathematical precision the site of incision. 3. It shows the number of calculi; this is of importance, because it occasionally happens that there are two or more calculi in the ureter, and possibly at different levels. 4. It shows the presence or absence of an associated renal calculus; a knowledge of this will obviate the embarrassment of a second operation.

I need hardly emphasize the fact that the plate shall be made, and especially be interpreted, by a competent radiographist.

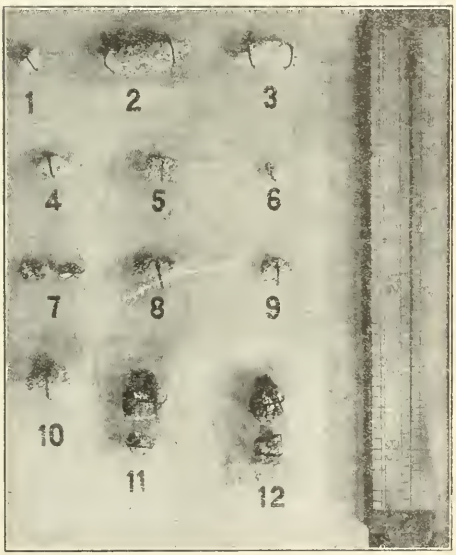
I am not unmindful of the occasional pitfalls which may arise in the interpretation of a given shadow, which may be found upon the plate in the course of the ureter, such as phleboliths, calcified glands, sesamoid bones, and foreign bodies in the intestinal tract; but I have no hesitancy in so stating my standpoint that, given a clear history of a urinary calculus and the presence of a shadow in the course of the ureter, the evidence is overwhelmingly in favor of calculus. If doubt exists whether a given shadow proceeds from the ureter or not, additional evidence may be obtained by passing a styletted ureteral catheter to the point of obstruction and again subjecting the patient to the *x*-rays. If the shadow is derived from something extraneous to the ureter, the shadow of the catheter will be found to lie to one or the other side of it. Nor am I unmindful of the difficulty which is occasionally met with, when dealing with uric acid calculi, which, as is well known, are less impervious to the *x*-rays, than calculi of other composition. Personally, I have found, however, that a calculus will always throw some kind of a shadow upon the plate, no matter what its composition (this is perhaps due to the fact that absolutely pure uric acid calculi, without any admixture, are extremely rare) provided necessary care is taken in the exposure.

Treatment.—It may be laid down as a self-evident axiom that no calculus should be permitted to stay indefinitely in the ureter; the eventual outcome must be an infection of the kidney with its inherent dangers. The only question still sub judice is, to determine at what period in the course of the dis-

ease surgical interference becomes necessary. Personally, I have made it a rule not to advise operation as soon as the diagnosis is made, but to observe the case for a short while, in order to allow natural forces full scope in the propulsion of the concrement. That this course was the proper procedure is proven by the following cases:

Case I. Wm. W., 63 years of age, consulted me Dec. 16, 1905, complaining of attacks of pain in the lumbar region and right side of the abdomen, with typical radiation to the testis and bladder; during the past four months there has been a more or less constant hematuria. The *x*-ray showed a small calculus in the pelvic portion of the ureter. One month later, after an unusually severe attack, he voided a calculus of the shape and size of a grain of wheat.

Case II. Sarah W., 30 years of age, consulted me Feb. 20, 1908, complaining of attacks of pain in the right side of the abdomen, which began about two years ago, and have recurred at increasingly frequent intervals, and were accompanied by bloody urine. *X*-ray revealed the presence of a ureteral



calculus, approximately one inch from its vesical end. With the next attack, one week later, the calculus was extruded into the bladder and was voided with the urine. (Fig. 1.)

Case III. S. F. This is the second calculus of Case VII, to which the reader is referred.

Case IV. Mrs. B. N., 40 years of age, consulted me in May, 1907, for symptoms pointing to a left-sided renal calculus. An *x*-ray plate revealed the presence of a large calculus in the pelvis of the right kidney, and also of a pea-sized calculus in the upper part of the left ureter. She was successfully operated for the calculus in the right kidney in July, 1907. Two weeks after her discharge from the hospital she passed the left-sided ureteral calculus, after an attack of very severe renal colic.

In addition to the above, I have observed perhaps a half-dozen small calculi, which were safely passed and voided after attacks of renal colic, but the proof of their ureteral impaction is lacking because no *x*-ray exposure was made.

It is often surprising to see what nature can do in the propulsion of ureteral concrements. One of the smallest calculi in my series, Case VIII, was absolutely impacted in the ureter, within one and one-half inches from the renal pelvis, causing such severe attacks that its removal became imperative; on the other hand, the largest calculus in my series (to be shortly described) was passed into the bladder, six weeks after I had first seen the patient, and after I had told him that it was impossible for a calculus of such size (as determined by the *x*-ray) to pass into the bladder.

Case V. Benj. A., 33 years of age, was referred to me in February, 1906, by Dr. Moskiewitz, with the following history: Patient has had two attacks of gonorrhea, twelve and fourteen years ago respectively, and has retained since then a slight mucopurulent urethral discharge. For the past year micturition has become more and more difficult, being painful and slow. In addition the patient complains of a constant pain in the back and left side of the abdomen. Urine is alkaline and loaded with pus cells. The urethra admits a No. 13 F. sound. Diagnosis, stricture of the urethra, and left-sided pyelitis and pyelonephritis.

Operation Feb. 12. Internal and external urethrotomy. On Feb. 21 patient had a very severe attack of left-sided renal colic; *x*-ray examination revealed the presence of a large ureteral calculus opposite the spine of the ischium. Patient was discharged Feb. 28, with instructions to return in three weeks for the removal of the ureteral calculus.

He was readmitted to the hospital April 30. Since his discharge he has had frequent attacks of renal colic, on an average every two or three days. Twelve days ago there was a very severe attack, which lasted forty hours. When the attack was over patient found that he could not void his urine, and had to be catheterized; thereafter he could urinate only when lying prone upon his back. A stone searcher and the cystoscope revealed the presence of a vesical calculus, while the *x*-ray showed that the previously seen ureteral calculus was now lying transversely in the bladder.

Operation May 2. Suprapubic cystotomy and removal of calculus. (Fig. 2). Discharged cured May 15.

It is perhaps superfluous to mention that the one drug indicated in an attack of renal colic is morphine in liberal doses. I have also, I believe, seen favorable results from hot applications.

I have had no personal experience with the methods of assisting nature to propel the concrement by injecting lubricants, such as sterilized oil or glycerin, through a ureteral catheter into the ureter, or even behind the calculus; but I mention it for the sake of completeness, and because occasional good results have been reported from it.

Calculous anuria, whether the anuria is reflex and caused by a unilateral impacted calculus, or by a bilateral impacted calculus, is an indication for immediate operation. At this point I wish to go on record that the so-called reflex anuria due to a calculus in one kidney is, in my opinion, a much-talked of, but exceedingly rare phenomenon, and that the vast majority of cases of complete anuria due to ureteral causes, are due to either bilateral obstruction or to obstruction in one functionating kidney, from either acquired or congenital causes. I have found but few authentic cases of so-called reflex anuria which are valid on careful analysis. Formerly I advocated and practiced as an emer-

gency measure the operation of bilateral nephrostomy in these cases; at present, however, I believe that where prompt facilities for the taking of an *x*-ray plate are had, as in every large hospital, the immediate operation of ureterolithotomy, single or bilateral, as the case may be, is far preferable.

Thus far it has been my good fortune to observe and operate four cases of anuria, of which the following was due to calculous ureteral obstruction:

Case VI. Morris L., 48 years of age, was admitted to Mount Sinai Hospital Nov. 25, 1903, with the following history: Five years ago patient had a typical and severe attack of right-sided renal colic; he also thinks that there existed at the time suppression of urine for a few days, but his recollection is not clear upon this point. Two years ago he was laid up for two weeks with an attack of lumbago (?). During the past year he has had occasional attacks of sharp pains, which he refers to the neck of the bladder, during which the urine was suppressed; after these attacks had passed away he found small calculi in the urine.

On Nov. 16, nine days ago, he was seized with a sudden, sharp, severe pain in the left side of the abdomen, which required the administration of large doses of morphine, but persisted in spite of it up to the time of admission. Urination continued normally until Nov. 22 (72 hours before admission), when complete suppression ensued and has persisted, except for a few drops of blood passed Nov. 23 (two days ago). Physical examination is negative, but is unreliable on account of extreme obesity. There is a urinous odor about the patient, and slight edema of the lower extremities is also present.

Nov. 25. Immediate operation; bilateral nephrostomy. No calculi were present in the kidneys, but an obstruction was found in the left ureter, about seven inches from the pelvis of the kidney, and one on the right side about six inches from the pelvis. The patient reacted surprisingly well from the operation, except for the discomfort of the urinous discharge, requiring frequent and bulky dressings. On Dec. 5 patient voided one and one-half ounces of urine spontaneously for the first time, and was up and about in the ward.

On Dec. 18, after a hitherto nonfebrile course, the temperature rose to 104.2° F., and this occurred every two or three days without any apparent cause. Therefore, on Dec. 29 a slightly curved glass tube was introduced into the right nephrostomy wound, and through this various sized bougies were introduced; all were obstructed at about six inches from the cutaneous incision; the ureter was irrigated by means of a small catheter, the fluid returning immediately, and being very foul in character. The same procedure was repeated on the left side, but on this side the bougie could be introduced to a much greater depth. Upon this examination it appeared probable that a ureteral obstruction existed on the left side at the vesical end of the ureter, and upon the right side approximately six or seven inches from the cutaneous incision. An *x*-ray plate taken was not satisfactory. Cystoscopy on Dec. 30, which was very difficult, the capacity of the bladder being only about two ounces, seemingly corroborated the above findings; the right ureteral opening was normal, but no urine escaped from it; upon the mouth of the left ureter there appeared to be a small whitish mass about the size of a pea, which was looked upon as an impacted calculus.

Operation Jan. 4, 1904. Ureteral guides were first introduced through the nephrostomy incisions as far as the obstructions permitted. Suprapubic cystotomy then performed, in order to remove the assumably impacted calculus from the mouth of the left ureter; none was found, however, but the suprapubic incision was utilized for the passing of ureteral catheters, both of which readily passed up an equal distance, about two inches. This was followed by an extraperitoneal ureterotomy upon the right side, removing the larger one of the two calculi (Fig. 3).

On Jan. 5 the patient voided twice voluntarily two and two and one-quarter ounces respectively. All incisions were firmly healed in fourteen days, therefore the final operation was performed on Jan. 18; this time consisting of an extraperitoneal ureterotomy on the left side, removing the smaller calculus (Fig. 4) from just below the linea arcuata. Patient was discharged cured, with all five incisions firmly healed on Feb. 10, voiding all urine through the natural channels.

The method of procedure for removal of a ureteral calculus depends primarily upon the exact point where the calculus is located. The various procedures possible suggest themselves readily, and I shall merely outline these methods in the briefest manner.

1. Calculi projecting through the vesical mouth of the ureter may be dislodged by manipulations with the ureteral catheter, through a cystoscope. This was possible in one patient of my series.

Case VII. Sam F., 34 years of age, consulted me in September, 1904; his chief complaints were right-sided abdominal pain, accompanied by hematuria; the latter had existed for three days, and was very profuse. On cystoscopic examination I saw with the greatest clearness the whitish calculus protruding from the swollen mouth of the right ureter, and dislodged it with the beak of the instrument. On emptying the bladder the calculus (Fig. 5) was also voided.

Two years later similar symptoms appeared, and this time the *x*-rays revealed the presence of a calculus in the pelvic portion of the right ureter; this was also passed by natural forces. (Fig. 6.)

In the female calculi may be dislodged by the finger within the urethra, or through a perineal boutonnière in the male. From the bladder they may be removed by any of the many well known methods.

2. Calculi situated in the intramural, that is that part of the ureter which lies within the wall of the bladder, usually require for delivery a preliminary suprapubic cystotomy. The mouth of the ureter can then be either dilated bluntly sufficiently to permit the extraction of the calculus, or if this is impossible the mouth of the ureter may be incised. This procedure is perfectly safe for a distance of one centimeter; beyond this, however, there is danger of injuring the peritoneum.

3. Calculi situated in the juxtavesical portion of the ureter have been removed by incision through the vagina, and once, also, with a fatal issue, through the rectum; removal by the sacral route has also been suggested; but I fail to see any advantage in these methods over the extraperitoneal method, which I shall shortly describe.

4. Calculi in or near the renal portion of the ureter can be best reached through one of the normal kidney incisions.

Case VIII.—Daniel D., 47 years of age, was referred to me in July, 1903, by Dr. S. Tandlich, with the following history: Patient has had a constant

pain in the back for the past fifteen or twenty years, which he has been in the habit of relieving with hot applications and diuretics. Twelve days ago he has had his first typical and very severe attack of renal colic; these attacks were repeated daily three or four times. The urine contained pus and red blood cells.

Operation, July 17. Nephrotomy followed by ureterotomy; two impacted calculi (Fig. 7) being extracted from the ureter, about two inches below its renal attachment. Patient was discharged cured August 11.

5. For calculi which are impacted in the pelvic portion of the ureter, and by this I mean that part of the ureter which extends from its intersection with the common iliac artery down to its vesical attachment, three methods of attack have been advocated. (1) By an intraperitoneal incision, (2) by an extraperitoneal incision, (3) by combined intra- and extraperitoneal incision.

Personally I believe that there is no question at all that the possibility of peritoneal infection by extravasated urine almost forces us to adopt the extraperitoneal method as the method of choice, even though this route is a trifle more difficult than the intraperitoneal method.

The procedure as I have used it is, briefly, the following: First of all I have adopted the plan to always take an *x*-ray upon the day of the operation, in order to determine first, whether the calculus is still present, and, secondly, whether or not the calculus has shifted its position. This safe guard sometimes obviates unnecessary embarrassment.

An incision about three inches long is then made upon the abdominal wall, the general direction being parallel with the fibers of the aponcurosis of the external oblique. The incision through the internal oblique and transversalis is made either at the outer border of the rectus, or a trifle more laterally through their fibers. The transversalis fascia is divided in the same direction. I have not found that division of the fibers of the muscles predisposes in any way to hernia; a firm and correct suture of the fibers is easily done, and the amount of drainage necessary can be reduced to a minimum. It is I am sure, hardly necessary to mention, that suitable care be exercised in conserving the integrity of all the nerves which are met with.

The peritoneum is now bluntly separated from the iliac fossa and retracted toward the median line, exposing in their order the common, external, and internal iliac, and spermatic arteries with their accompanying veins. Search is then made for the ureter. It is well to remember that in every instance the ureter is attached by fibrous bands to the peritoneum, and it is upon the peritoneum and not upon the posterior abdominal wall that the ureter will be found. The ureter can then be isolated either in an upward or downward direction, until the calculus is reached. If the calculus is at a great depth, an obstacle to further progress will be met with, in the previously described band running transversely inward; this can be readily overcome by nicking its sharp edge (occasionally a small vessel may have to be ligated). Attention should also be called to the fact that not infrequently dense adhesions are met with in the neighborhood of the calculus, on account of a coexisting periureteritis, which require some care in separation.

After the calculus has been reached, it is firmly grasped between two fingers, the ureter is incised and the calculus extracted. If it is situated at great depth, an attempt, successful in most instances, may be made to manipulate it to a higher level. This not only facilitates its removal, but also the subsequent closure of the ureteral incision. The incision in the ureter is then sutured; this is possible in most instances, but even if not, no harm will result, inasmuch as any resulting fistula always closes in due time. As suture material I have always used either fine iodine or chromicized catgut, passed so as not to include the mucosa. Prior to closing the ureter it is wise to pass a ureteral catheter both downward and upward, in order to convince one's self that the lumen is free.

Just a word regarding drainage. In my earlier cases I always used a cigarette drain, made of gauze and rubber tissue; but having abandoned these in our appendicitis work for a rubber tube drain, through which a strip of gauze has been pulled, I adopted this form of drain also for ureterotomy wounds. This was eminently successful, up to a recent case (Case XII) of bilateral ureteral calculus, in which the tubes caused a large slough in the walls of both external iliac arteries, with secondary hemorrhage, necessitating simultaneous ligation. Since this accident I have again had recourse to cigarette drains.

The peritoneum is permitted to fall back into place, and the wound is now sutured in layers.

The usual after treatment is carried out. Occasionally, when the ureteral suturing has not been sufficiently exact, the dressings may have a slight urinous odor, but, as a rule, not even this much occurs to mar a primary union. The drain is removed according to indications, and in most instances the patient leaves his bed on the tenth or twelfth day, and is discharged with a firm scar in two weeks.

I have operated by this method the following cases:

Case VI.—This has already been described when speaking of calculous anuria; a bilaterial ureterolithotomy was performed.

Case IX.—Julius R., 33 years of age, was admitted to Mount Sinai Hospital, June 3, 1906, with a history of frequent attacks of renal colic during the past eleven months. The urine contained red blood cells and pus cells. An *x*-ray plate showed a calculus near the vesical end of the right ureter. He refused operation at this time but returned again June 27, with the most severe attack yet, and was operated upon June 28. Lateral extraperitoneal ureterolithotomy, with removal of a calculus from the ureter about half an inch above its vesical end (Fig. 8).

Case X.—Louis B., 27 years of age, was admitted to Mount Sinai Hospital, Nov. 27, 1906, with a history of very severe and frequently repeated attacks of renal colic and hematuria. An *x*-ray examination revealed the presence of a calculus impacted in the left ureter about 4 cm. above its vesical end. Operation Nov. 30. Extraperitoneal ureterolithotomy, with the removal of a calculus (Fig. 9). Patient was discharged cured Dec. 16.

Case XI.—Samuel J., 24 years of age, was referred to me by Dr. Rosenbaum in Sept., 1908, with the following history: His illness began about four years ago with attacks of left lumbar pain. At first these attacks occurred at intervals of several months, but gradually they have increased in frequency, and began to radiate to the penis and testis; during the attacks there are always severe hemor-

rhages. Examination is negative, but for tenderness in the course of the left ureter. An *x*-ray plate showed a calculus in the left ureter about half an inch below the sacroiliac synchrondrosis. Operation Sept. 10, extraperitoneal ureterolithotomy with removal of a calculus about one and one-half inches from the bladder (Fig. 10).

Case XII.—Because of the unique interest of the case I have published it in full detail in the *Annals of Surgery*, December, 1908.

Samuel W., 36 years of age, was referred to me in March, 1907, by Dr. B. Lefkovics with the diagnosis of nephrolithiasis. An *x*-ray plate taken at the time revealed the presence of two calculi in the pelvic portion of each ureter, and a suspicious shadow in the region of the left kidney. Operation was advised, but the patient passed out of my observation, and when he again returned to me he stated that he was operated upon by Prof. Zuckerkandl, of Vienna, for the renal calculus; this operation, however, did not bring about any amelioration of his symptoms. Patient entered Mount Sinai Hospital and was operated upon July 20, 1908. The operation consisted of a bilateral extraperitoneal ureterolithotomy, removing two calculi (Fig. 11) from the pelvic portion of the right ureter, and two calculi (Fig. 12) from the left. Primary union ensued, but while dressing the patient July 27, a tremendous hemorrhage occurred upon removing the drainage tubes, necessitating simultaneous ligation of both external iliac arteries. In spite of the enormity of the accident, patient made an absolutely uneventful recovery, and was discharged cured September 4.

The foregoing is by no means a complete summary of the cases of ureteral calculi I have seen; I find in my records at least five more cases, in which the diagnosis of ureteral calculus was made and substantiated by the *x*-rays; but they either still carry their calculi or have been operated upon by other surgeons; they have therefore not been included in my statistics.

Prognosis.—Just a few words regarding the prognosis of impacted ureteral calculi. I do not believe I shall meet with much opposition when I state that calculi obstructing the ureter for any length of time will sooner or later be followed by an infection of either the pelvis or parenchyma of the kidney; and I need waste no time to explain what must be the consequences of this plan. On the other hand, the surgical removal of such calculi is followed by almost ideal results. The mortality in experienced hands is practically nil; the operation is comparatively easy of execution; the period of convalescence is rapid (not more than two weeks as a rule); the patient is immediately relieved of all distressing symptoms, and if the function of the kidneys has not been seriously interfered with by the disease, full return to health will be very probable; finally the danger of a subsequent hernia is so slight, that it does not even merit serious consideration.

Duration of Immunity After Injection of Anti-Diphtheretic Serum.—Sittler says that prophylactic immunization maintains a lasting result for a longer time (three to five weeks and more) when the immunized children do not come too often into contact with those suffering from the disease or convalescents; such precaution is necessary also on the ground of not making immunized persons carriers of the bacillus, and so spreading the infection. If immunized children be detained amongst those affected with diphtheria the immunity can only last a very short time (fourteen days).—*British Journal of Children's Diseases*

MASTOIDITIS FOLLOWED BY INFECTED SINUS THROMBOSIS IN A YOUNG PREGNANT PATIENT:

OPERATION; ABORTION; PULMONARY ABSCESS; CEREBRAL HERNIA; OTHER COMPLICATIONS; RECOVERY.*

By M. D. LEDERMAN, M.D.

NEW YORK

ATTENDING OTOLOGIST AND LARYNGOLOGIST LEBANON HOSPITAL; ADJUNCT PROFESSOR DISEASES OF THE NOSE AND THROAT, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL; FELLOW NEW YORK ACADEMY OF MEDICINE.

The serious complications following a chronic purulent otitis in a young pregnant patient have prompted me to report the following history, as being worthy of record.

L. O., single, 15 years of age, was admitted to the medical service of Lebanon Hospital in August, 1908, for observation. She complained of general weakness, frontal headache, and fever. The family physician had referred her to the hospital with a tentative diagnosis of typhoid fever. Her mother had died of pulmonary disease some years ago, and except for an attack of measles at the age of two years the patient had been in good health up to the present illness. Her father and younger sister were alive and in good health. She began to menstruate at the age of thirteen. This function had continued regularly up to four months ago, when it ceased.

The physical examination showed a large, well developed patient for her age, with nothing unusual in the thorax except a few sonorous râles heard over the chest, but not localized. A globular mass was felt in the abdomen, in the median line, extending to the umbilicus and simulating a five months' pregnant uterus. Other organs were found normal. Vaginal examination revealed an absence of the hymen, cervix soft and admitting a finger. Fundus of uterus extended to the umbilicus. Breasts were large, soft, and contained colostrum. A diagnosis of pregnancy was made, and though a temperature of 103° per rectum was recorded on admission, nothing further was found at this time to account for the fever. The urine was very carefully examined, and but for a very slight trace of albumin nothing abnormal was noted.

During the few days following her admission a number of chills appeared in regular intervals, followed by fever and sweats. The bedside report showed that the chills occurred morning and evening, and some lasted for several minutes. After one of these prolonged chills, the temperature reached 107.2°, and then gradually declined to normal until the appearance of another chill, when it again climbed five and six degrees. The temperature chart showed a decided septic wave. Blood examinations for malarial and other microorganisms, together with the Widal reaction, were negative. The differential blood count, however, gave a pronounced leucocytosis and a marked increase in the polynuclear cells. Nausea and vomiting were present, together with headache over the frontal region.

On August 5 the girl had a comfortable morning with no pain anywhere. Temperature normal, but had three chills in the afternoon, followed by a rise in temperature to 105°. The fever was followed by considerable sweating. After a tepid

*Patient exhibited at Otological Section, New York Academy of Medicine, November, 1908.

sponge bath, the temperature gradually subsided.

August 6 the patient complained of pain in the right iliac region, and this area was sensitive to pressure. A complete physical examination was again made by the house physician, and nothing abnormal was found. An inspection of the ears, however, revealed a foul-smelling discharge in the canal of the right ear. The mastoid tip was found sensitive to pressure. With the evidence of a chronic aural suppuration, the existence of which had not been mentioned in the history by the patient, the septic nature of the symptoms was appreciated.

On August 7 the patient came under my observation. The report over the 'phone stated that there was an increase in the tenderness of the mastoid process, with the appearance of slight edema at the tip. There was rigidity of the neck muscles on the right side, together with pain along the sternomastoid muscle on pressure. The aural discharge was profuse and foul-smelling, and showed streptococcus infection. Examination of the eyes revealed approaching choked disc. The morning temperature registered 102°, pulse 128, respiration 28.

With the above characteristic history a diagnosis of mastoiditis with septic sinus thrombosis was made, and the patient was prepared for operation. At two o'clock on the afternoon of the same day, I examined the girl for the first time and found conditions as above stated. Cerebration was active. The patient complained of severe frontal headache, which was aggravated on percussing the right parietal region with the finger. The swelling in the region of the mastoid was not marked, but tenderness over the emissary vein and along the neck was decided. No cord-like sensation could be felt. Examination of the ear showed a canal filled with foul-smelling pus, with a large perforation involving the inferior two-thirds of the membrane. The middle ear was filled with granulation tissue, with necrosis of the upper posterior bony wall. With the good ear closed, the voice was not heard distinctly. The patient's general appearance was septic. Temperature 106°, pulse 148, respiration 36.

The usual curvilinear mastoid incision was made from the mastoid tip to above the attachment of the auricle. After elevating and retracting the periosteum, the cortex was seen discolored at the suprameatal triangle. With the removal of a few chips of bone, a dark mass appeared in the wound. This proved to be the thrombosed sinus, close to the meatal wall. It occupied a very superficial position, extending superiorly for a distance of half an inch above the plane of the upper bony wall of the external auditory meatus before making its turn posteriorly. Foul-smelling pus was seen coming from under the sinus anteriorly. The external bony covering of the sinus was removed with the rongeur forceps from half an inch beyond the knee, to as near the bulb as possible. The presenting wall of the sinus was gangrenous in appearance, and a portion had sloughed. Through this opening the thrombus could be seen. The diseased wall of the sinus was cut away with scissors for nearly the entire length of the bone opening.

The upper portion of the infected clot was then removed with a dull wire curette until free bleeding occurred. This was checked with the usual iodoform tampon. Though a return current of blood followed the gentle removal of the thrombus in the bulb end of the sinus, it was not profuse, so we decided to ligate the internal jugular vein low in the neck, on account of the previous septic symptoms. The vein was ligated by Dr. Henry Roth, an attending surgeon of the hospital, who kindly assisted. Ligatures were applied just above the clavicle about an inch apart. The vein promptly filled with blood. After the neck wound had been cleansed it was sutured.

The mastoid wound was then thoroughly cleansed of diseased tissue, and a portion of the posterior canal wall was removed to a plane below the visceral wall of the sinus. Considerable bone posterior to the sinus was taken away with the rongeur and curette. The excessive granulation tissue from the middle ear was also ablated. After cleansing the canal and posterior wound with peroxide of hydrogen and saline solution, an iodoform gauze drain was placed in either end of the sinus opening, together with the usual packing in the bone wound and auditory canal.

August 8. The midnight temperature (eight hours after operation) had reached to 99°, pulse 112, respiration 26. By four o'clock A.M. it fell to 96.2°, pulse 86, respiration 24. It remained there for twelve hours, then gradually rose to 102°. During the next two days the patient felt quite comfortable.

On August 10 severe cramp-like abdominal pains set in during the early hours of the morning, and at four o'clock A.M. the patient was delivered of a five months' fetus. During the afternoon the temperature had reached 103°, and though the young girl had passed through a very trying ordeal, it was thought best to change the dressings without disturbing her position. The wound showed considerable suppuration, especially in the region of the bulb. The discharge was foul-smelling, of an ammoniacal odor. Peroxide of hydrogen was poured into the wound, followed by warm saline solution. This was repeated until effervescence stopped. Iodoform drains were replaced in both sinus openings. The neck wound seemed to be in good condition. Following the dressing, the temperature gradually subsided to 101°.

August 12. Some pain was experienced in the right side of the chest, especially on percussion near the sternum. Many moist râles were heard on this side in the axillary line. The mastoid wound looked somewhat cleaner above, but considerable purulent odoriferous discharge still present in lower sinus opening. Same treatment carried out.

August 13. The neck wound had become infected, and about two ounces of pus was evacuated from a pocket which led toward the sternum. The usual rubber tube drainage was employed. The temperature fluctuated between 103° and 104°. Paroxysms of cough appeared with some mucopurulent expectoration. No chills had been observed since the operation.

August 14. Mastoid and neck wounds progressing nicely. Cough very annoying. Expectoration is foul-smelling and of a distinctly purulent character. Moist râles heard in right chest. Diminished and distant breathing, and dullness over right base.

August 15. On attempting to assume a sitting posture in bed the patient had a severe paroxysm of cough, accompanied by an unusual quantity of dirty-looking malodorous pus expectoration. The coughing stopped as soon as the recumbent posi-

tion was resumed. The breath at this time was very fetid. A diagnosis of metastatic pulmonary abscess was made, though my medical associate was inclined to believe that an empyema of the right side had appeared. The sputum was examined microscopically, but only streptococci were found, and occasionally an elastic tissue fiber was seen, together with many pus cells, some red blood corpuscles, and numerous epithelial cells. We did not think it advisable, however, at this time to make an exploratory puncture of the chest, for fear of infecting the pleural cavity.

For the next five days the patient was as well as could be expected from existing conditions. The temperature remained around 104°, but the pulse was good in quality and regular.

August 20. The general appearance of the patient had improved materially. The anxious expression had disappeared and the young sufferer was beginning to take an interest in her surroundings. The neck wound was closing satisfactorily and the mastoid opening appeared to be progressing favorably, except for a bulging of the visceral wall of the sinus in its descending portion. This seemed to be due to intracranial pressure. As the temperature still registered around 103°, the possible existence of a subdural collection of pus was suggested, and the internal sinus wall in its most prominent portion was incised. Considerable clear fluid came away, together with what appeared to be some disintegrated brain tissue. Exploration through the incision failed to reach any pus cavity. Later on, however, a cerebral hernia about the size of a walnut developed through the opening of the sinus, without unpleasant consequences. Following this treatment, the temperature subsided somewhat, and though for three days there were fluctuations from 99° to 102.4°, it reached 101° on August 30, and gradually declined from that date until it reached normal, on September 17.

During the interim the mastoid wound was dressed daily for three weeks. Both ends of the sinus were cleansed with the peroxide and warm saline solution, and were drained with iodoform gauze until the parts assumed a healthy appearance and all odor had disappeared. A separate pad of gauze was placed over the cerebral hernia and gentle pressure was applied. At no time did this complication give any annoyance, except for its presence near a suppurating wound, and as the bony cavity filled in, the hernia gradually disappeared.

The neck wound was healed on August 23. There was still considerable cough with foul-smelling purulent expectoration. Physical examination found decided dullness at the right base of lung, with distinct bronchial and diminished breathing. A radiograph taken at this time showed an opacity of the right side, extending from the eighth rib to the base of the lung. The lymph nodes on both sides were enlarged, and the heart was displaced toward the left.

On September 8, the right chest was aspirated posteriorly in the tenth interspace, and about 2 c.c of clear serous fluid was obtained. This was examined for tubercle bacilli, but none were found.

September 15. The pulmonary symptoms began to improve and the sputa became less purulent. The area of dullness was diminishing.

September 20. Lungs gradually clearing. Temperature normal. Patient out of bed.

September 22. Severe toothache appeared. Right molar was found to be diseased, and the surrounding tissue much swollen. An alveolar abscess was incised, and a mouth-wash was employed. This local infection lasted for six days, without causing further elevation of temperature or other symptoms. On October 3 the patient was out of bed and going about the ward. Lungs almost clear.

October 11. Discharged from hospital with operative wounds healed, but ear still discharging. The treatment of the middle-ear disease was continued at my office. Considerable granulation tissue was removed at a number of sittings under cocaine anesthesia. Dry treatment was carried out, and the edges of the large perforation and all granular appearing areas in the tympanic cavity were touched with a liquified trichloracetic acid.

In about six weeks the ear was dry, with the drum almost healed over. Hearing for ordinary voice was very good. The young girl's general health had evidently recovered rapidly from her severe sepsis of two months' duration.

Fortunately I am able to report this unusual case as one cured by surgical intervention, though the latter was somewhat delayed waiting for indicative symptoms. The question of early detection of sinus involvement is an important one. The recent bacteriological observations and conclusions of Libman (*Archives of Otology*, Vol. XXXVII, No. 1, 1908) should be of material assistance in determining whether or not the sinus should be explored in cases of suggestive symptoms at the time of a mastoid operation, or when such symptoms appear after operation. In his remarks on the significance of blood cultures, he states that a positive blood culture indicates a general invasion; a positive streptococcus blood culture in his experience nearly always points to the presence of sinus thrombosis.

In a certain number of cases in which the aural symptoms are not of sufficient intensity to account for existing symptoms, the presence of bacteria in the blood may give the indication to open the mastoid and explore neighboring tissue. Four cases are cited in corroboration of the above statement, showing how valuable blood cultures are in aural surgery.

THE CONSERVATIVE TREATMENT OF SOME TRAUMATIC INJURIES OF THE EXTREMITIES.*

By WALTER T. DANNREUTHER, M.D.,

NEW YORK

SURGEON, ST. ELIZABETH'S HOSPITAL; ASSISTANT SURGEON, RED CROSS HOSPITAL; ASSISTANT SURGEON, ST. BARTHOLOMEW'S CLINIC; ASSISTANT GYNECOLOGIST, WEST SIDE GERMAN DISPENSARY.

I PRESENT this subject for your consideration this evening with the hope that you will freely comment upon and criticise my remarks, and with the expectation of deriving a great deal of valuable information from the discussion which is to follow. In the limited time at my disposal, I naturally cannot refer to many varieties of traumatic injuries, and shall be compelled to confine myself to the citation of a few illustrative cases and make them the basis for the subsequent conclusions. These case histories may cause us to reflect upon the fact that

*Read before the Tri-Professional Medical Society, New York City, March 16, 1909.

perhaps occasionally a part of the human body is sacrificed unnecessarily; that possibly we not infrequently might avoid an amputation or other destructive operative procedure by carefully weighing in the scales of our judgment all the facts, and then augmenting the side of conservatism with a little extra pressure. I am afraid that many of us are at times inclined to hasten operative measures unduly and lean toward radicalism. However, the patient's life should always concern us most; and next in order, the injured part. I beg your indulgence for a few moments in which to briefly outline the case records.

Case I.—X. J., a well nourished and developed man, age 45, was admitted to the hospital on the morning of June 17, 1906. He had been working on a boat, and while making fast a hawser, the cleat had broken and his leg caught in a coil of rope. There was considerable shock on admission, but the patient rallied well and by late in the afternoon was in fairly good condition. There was a compound comminuted fracture of the tibia and fibula, the periosteum was extensively torn and stripped up, part of the tibialis anticus muscle ruptured, and the anterior tibial artery lacerated. In fact, the hemorrhage from the latter was so profuse that a tourniquet was found necessary to control it. The calf of the leg was apparently intact. The possibilities of recovery without amputation, as well as the dangers of infection, necrosis, and septicemia were fully explained to the patient. He elected a conservative operation and was immediately transferred to the operating room and anesthetized. The leg was shaved, thoroughly cleansed with green soap, and the wound freed of all visible foreign material and washed out with peroxide. The several lines of fracture were principally longitudinal, and five or six fairly large spicules which were entirely devoid of periosteum were removed. With an assistant holding the foot in proper position, the rent in the artery was carefully sutured, as much as possible of the periosteum was united, and the ruptured muscle fibers were brought together. The skin margins were approximated, and drainage was instituted. A heavy wet gauze dressing and two lateral splints were applied, and the whole placed in a fracture-box. Continuous irrigation was maintained by means of a suspended tin pail with several small holes in its bottom through which strips of linen had been forcibly pulled. By the end of the first week more contusion than was apparent in the beginning had manifested itself, and for eight or ten weeks there was an exposed bony surface an inch or two in diameter. At the end of this time the wound began looking healthy except for a small sinus on the outer side. This was dressed daily with balsam of Peru and glycerin, until the patient's discharge from the hospital, January 22, 1907. Two or three small spicules were extruded during the summer, after which the sinus closed. In the spring of 1908, less than two years after the accident, the patient reported that he had perfect confidence in the leg, and, except for a slight limp, it caused him no inconvenience whatever

Case II.—C. P. P., an exceptionally well nourished and developed negro, age 34, was admitted to the hospital October 28, 1906. His right elbow had been caught in an asphalt crusher, but he was conscious and reacted strongly on admission. The soft parts were extensively lacerated, the external condyle of the humerus completely torn off, the ulna fractured just below the coronoid process and again at the junction of the upper and middle thirds, and there was a comminuted fracture of the neck of the radius. The elbow joint was opened and exposed, and the wound was filled with dirt and grease. Fortunately the soft parts on the inner side had almost entirely escaped injury, so that the continuity of the brachial artery remained unbroken and the nutrition of the part was not interfered with to any great degree. Nevertheless, the patient was advised to consent to an amputation above the elbow joint, although he was informed that there was a chance of his recovering should he refuse it. It seemed exceedingly improbable that, with the entire large synovial membrane of the elbow joint exposed, septicemia could be averted. The patient, however, preferred to risk his life in an effort to save the arm. He had always enjoyed good health, had no bad habits, and had a cheerful disposition, all of which were points in his favor. The joint was accordingly carefully cleansed, and the external condyle of the humerus extracted with a pair of thumb forceps. A heavy wet dressing was applied to the whole arm from the shoulder to the fingers, bandaged to a straight splint, and a continuous irrigation of physiological saline solution, as in Case I, sustained for six weeks. The dressings were renewed daily and the temperature did not rise above 101° at any time. Drainage from the joint was copious, being favored by sprinkling the wet gauze with glycerin. After the continuous irrigation was discontinued, the external membrane which is found in direct approximation with an egg-shell was teased into small pieces under saline solution and placed upon the raw surfaces. Over this gauze spread with ichthyol ointment was applied, around which was wrapped the wet dressing. These dressings were changed every day, and about once a week the angle of the splint was slightly increased. The splint and dressings were continued until the patient left the hospital, April 15, 1907. Passive motion and massage were prescribed and the patient directed to persevere with them for a long time. In May, 1908, about eighteen months after the accident, he reported that he could use the arm surprisingly well; he could even feed a furnace with a shovel. There is a moderate amount of pronation and supination of the forearm, and about five degrees of motion at the elbow joint.

Case III.—Mr. X, age 60, while in a state of intoxication, had slipped from the steps of a moving train, and both feet had been run over, November 24, 1906. The patient was a chronic alcoholic, and in poor general health. For this reason, although the injury did not extend above the ankle joint on either foot, his family was advised to permit an amputation at the knee. This was absolutely refused, and we were compelled to do a double Pirogoff operation. Fairly good stumps were obtained and all went well for ten days; at the end of which time dry gangrene appeared on both sides. Immediate amputation higher up was once more strongly urged upon the patient's wife and friends, but was again rejected. Potassium permanganate dressings were applied constantly to the gangrenous areas and all our resources were drawn upon in an effort to improve the patient's general condition. Although he lived much longer than was expected, he demonstrated little improvement at any time, and finally died April 14, 1907, of hypostatic pneumonia.

Case IV.—Mr. Y., age 18, presented himself at the clinic, December 28, 1908. His right index

finger had been caught in some machinery and the terminal phalanx was almost completely severed. The soft parts were severely lacerated, the bone crushed, and generously intermingled with dirt and grease. The only rational procedure in this instance seemed to be to complete the amputation, which could easily have been done with a pair of scissors. But in spite of all arguments, the patient's consent could not be obtained. Consequently, the site of injury was cleansed and the foreign material removed as well as could be, tincture of iodine was liberally applied, and the finger was bandaged with a wet dressing to a splint. The gauze was changed and iodine injected every second day for two weeks and I was astonished to see that the severed end had united and appeared healthy. Except for the loss of the nail and a bad scar, this patient has a whole finger.

It would be a waste of time for me to reiterate all the well-known rules and principles to be observed in deciding whether to amputate or not when a limb has been seriously injured. I prefer simply to direct your attention to and emphasize the salient points illustrated in the foregoing cases which would incline one to adopt a conservative attitude after such experiences.

The essential prerequisites for a conservative method of treatment are: a good constitution, age under sixty, the integrity of at least a third of the circumference of the limb preserved, adequate blood supply to the site of injury and the part beyond, and a good nurse. Contributing factors are: perfect asepsis and antisepsis to the great est attainable degree, immediate restoration of the injured structures to their normal relations as far as possible, free drainage, and constant wet dressings. In the two latter lie our only hopes that the patient will not die of septicemia.

I have long advocated the use of glycerin in conjunction with wet dressings. It will be found a very valuable aid in keeping the gauze moist, and its powerful hygroscopic properties promote drainage and hasten sloughing.

The several sections of the membrane from the egg-shell, as applied to Case II served almost as well as skin grafts. At each dressing two or three little islands from the previous one would be found adherent. These proved to be an excellent foundation for the ultimate process of epithelial regeneration.

Undoubtedly, had we been permitted to amputate both legs in Case III at the knee in the first place, the likelihood of the patient's recovery would have been much greater. I felt that it was a mistake to leave the entire knee joint interposed between the site of injury and the body; the patient was advanced in age, alcoholic, and in poor health, so that gangrene seemed almost a certainty. I cited this case to demonstrate that I fully appreciate that there are many instances in which only a radical operation will afford the patient any chances whatever. Alcohol is the worst enemy of conservatism.

I have no comments to make on Case IV, except to remark that it is but another example of the efficacy of iodine as an antiseptic and an aid to healing processes.

Good nursing is of the utmost importance in the after treatment of these cases, and I take this opportunity to thank Mr. Chas. W. Moore, the nurse in charge of all the hospital cases I have mentioned for his efficient and faithful attention to them.

FURTHER RESEARCH REGARDING THE PHOSPHATIC INDEX OR THE PULSE OF THE NERVOUS SYSTEM.*

By J. HENRY DOWD, M.D.

BUFFALO, N. Y.

GENITOURINARY SURGEON, MERCY HOSPITAL.

It is not the writer's intention to change in any way the views expressed in the Medical Record of May 9, 1908. The opinion there expressed is maintained, as far as importance is concerned, but a more careful description may be of value in clearing up some points, at that time only vaguely referred to. In this connection it will be necessary to repeat a few paragraphs taken from that article:

"The mixture should change to a milky character at once, varying in degree as to the amount of phosphates present, etc. The phosphates should sink according to their specific gravity, as compared to that of the urine. That is, if small, light, and immature, they fall slowly, even at times remaining almost stationary, giving a general turbidity to the whole fluid. The size, weight, and appearance of the crystals are important factors to be considered. At times they fall to what may be considered a normal index, but in appearance the precipitate is fluffy, light, and easily movable upon agitation. Here they must be considered deficient, although they reach the normal index. Phosphates precipitated by an alkaline solution are fern-shape, when normal, about 5/8 of an inch in diameter (using 1/2 inch objective), but they vary greatly as to size and shape, at times being less than 1/8 of an inch, and having practically no formation."

Before attempting to analyze the above, it may be said that the phosphatic index, together with the size, shape, and appearance of the crystals, is analogous to a blood count with a hemoglobin estimation as made with the blood scale and the appearance of the corpuscles on the microscopical field. A comparison may be made as follows: The index, the amount in 20 c. c. of urine from a 24-hour sample (or the urine passed between 7 and 11 o'clock in the morning) will answer to the number of blood cells per cubic millimeter. The size, shape, and appearance of the crystals indicate the amount of nuclein and lecithin which they contain, the same as the blood scale shows the amount of hemoglobin present. Such being the fact, it at once must be clear that to take the phosphatic index and study the crystals carefully is as important as a blood count. In fact, in the writer's opinion it is more so, for the reason that disease is prolonged and recovery postponed more often on account of neurotic conditions than of blood changes.

Furthermore, blood examinations necessitate an expensive apparatus and most careful technique, whereas the reverse is true of the phosphatic index. Upon the addition of the alkaline solution (8 c. c. to 20 c. c. of urine), the mixture, if normal, should change to a milky character at once; the precipitate rapidly sinking, in ten minutes, the time allowed for an estimation, should appear in a semi-solid mass in the bottom of the tube, displacing three c.c. of the fluid. This phenomenon is liable to great variations, depending upon the size, weight, and number of crystals present. To be of aid in the diagnosis, prognosis, and treatment of disease, one must know why these crystals are small, light,

*Read at a meeting of the Central New York State Medical Society, Buffalo, N. Y., October 1908.

and diminished or increased in number. Briefly stated, the phosphates found in the urine are derived from the food, and their presence in the urine is influenced greatly by certain foods and drugs. Thus, there is a marked increase on an animal diet, and drugs like phosphorus, strychnine, and lecithin (which should be considered a food) increase them greatly, providing assimilation is normal. The urinary phosphates depend upon the decomposition of nuclein and lecithin, a class of bodies derived from the brain, nerves, amniotic fluid, yolk of eggs, spermatozoa, and certain vegetable substances. In other words, nuclein and lecithin are the food, the life of every nervovital cell, and the phosphatic crystals will show the amount present. That lecithin and nuclein exist in the nerve cell in reserve is shown when a person in a pronounced state of nerve excitement, lasting days or weeks, does not take food to speak of, yet the phosphates in the urine are greatly increased. Let the condition continue for some time, and it will be found that the crystals decrease in size, become light in weight, and may even go so far as to be practically amorphous.

In such a condition there may be no organic disease present, yet a person may have to take to his bed through extreme exhaustion. We are all aware what position the nervous system takes in disease, how the calm and robust withstand infections, etc., or rapidly recover, whereas it is exactly the reverse in the markedly neurotic. Generally speaking, in the first instance we find a normal index, crystals normal in size, weight, and appearance. This is easily explained by one fact, that there has been a normal demand upon the reserve. Individuals of this class seem to be in a way immune to disease, and when attacked by inflammation, etc., recover quickly, because, by reason of the nerve tone in the tissue, resolution is hastened. On the other hand, the low index with small, light, and at times imperfectly formed crystals, shows that nerve tone is diminished; there is practically no control of the vasomotor system.

A few brief remarks upon three or four cases will more clearly define the subject under consideration:

E. H. K. æt. 24. Symptoms complained of, urinating every 15 minutes to 3 hours during day and 3 to 5 times at night. No organic condition present; never venereal disease. Urinary examination 1010, acid minus, no albumin, sugar, casts, pus, or crystals; phosphatic index 4/5 too low, crystals badly formed.

Diagnosis: Polyuria, due to no control of vasomotor system, caused by nerve cell starvation.

Treatment: Eight raw eggs daily, phosphorus, strychnine, and cannabis indica. Result, in eight weeks: Urination perfect; index and crystals practically normal.

D. A. æt. 18. For six or seven years urinating every half to one hour daily and four to six times at night. No organic or venereal disease. Urine 1028: acid plus, no casts, pus, sugar, albumin, or crystals. Phosphatic index 1¾ times above normal, crystals normal, but small.

Treatment: Avoid all excesses, work, study, and athletics. Bromide of gold and arsenic three times daily. Result in two months: Normal urination; index and crystals normal.

J. H. Severe pain in shoulders and hip; no history of rheumatism. Urinary examination 1016, acid minus, no albumin, sugar, casts, or crystals. Index, 3/5 too low, no formation of crystals. Diagnosis, neuritis, due to nerve cell starvation.

Treatment: Raw eggs, phosphorus, and strychnine. There was no pain after forty-eight hours, and it never returned. Later examination showed index and crystals practically normal.

Mrs. P. æt. 27. Severe pain in the left ovarian region; prostration so marked she could scarcely attend to household duties. According to a previous examination by gynecologist, the left ovary was tied down by adhesion, and removal advised as only relief.

Urinary examination 1018, acid plus, no albumin, casts, or sugar, and only a few pus cells from the vulva. Phosphatic index one too high; crystals small but well formed.

Treatment: Bromide of gold and arsenic. In three weeks no pain, strength fully returned and feeling perfectly well. There has been no pain in the ovarian region in three years.

40 North Pearl Street.

HINTS ON FLUOROSCOPY AND RADIOGRAPHY.

By ASPINWALL JUDD, M.D.,

NEW YORK,

ADJUNCT PROFESSOR OF SURGERY AND RADIOLOGIST, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

To make a satisfactory fluoroscopic examination, a steady current, with a medium tube, is desirable. Too great a quantity of current will break down the vacuum in the tube. It is desirable for the best work that a room painted dead black should be used. The light should be turned off for from 3 to 10 minutes to allow the eye to adjust itself to the conditions before the current is turned into the tube, the patient previously having been placed before the tube in such a position that the rays will focus upon the point we desire to examine. No patient should be subjected to more than five minutes' exposure to the tube at one session, and, if possible, the individual idiosyncrasy of the patient to the ray should be established beforehand. It is quite possible to produce a severe burn in a susceptible person with a much shorter exposure.

Many conditions yield us clearer knowledge by means of fluoroscopy than by means of radiography. The size and condition of the heart, aneurysms, consolidations and cavities in the lungs, position of the diaphragm, the size of the liver, strictures of the esophagus, the size of the stomach, the movements of the intestines, the condition of the sinuses of the head—all can be determined with greater accuracy by this means. The use of subnitrate of bismuth, mixed with some food, such as apple sauce, to make a good bolus, is essential in determining stricture or diverticula of the esophagus, size and movement of the stomach and of the intestines. This is fed to the patient in teaspoonful doses after the eye has accustomed itself to and made out the condition as accurately as possible.

As will readily be understood, upon the position of the patient in front of the screen depends the clearness and position of the image. We start with the patient standing directly in front of the tube, and turn him from side to side gradually. By this means we determine the relative size and position of the shadows. It is well to remember that fluoroscopy and radiography is a study in the relative

value of shadows, and that it requires special training in order to arrive at definite conclusions. It is often necessary to make several sittings in a difficult case to determine accurately the meaning of the shadows presented to us.

Elaborate and special apparatus has been devised as an aid to fluoroscopy. It is, however, very expensive, and unless the student desires to go into this work very exhaustively, unnecessary.

Points on Radiography.—The art of radiography is probably the most difficult thing with which we have to deal in our study of the *x*-ray, and is almost impossible to acquire by means of didactic teaching, practical experience in the art being essential to arrive at any sort of success.

Two methods are in use in taking radiographs. One consists of relatively short exposures with a very high tube and a large quantity of current, the second relatively long exposures with a small quantity of current. The first will give sharper outlines to our shadows. The second will show better the varying textures of our tissues.

The conditions confronting us with patient, tube, the machine for exciting the electric current, and the plate, are all such varying factors, that to give any definite rule is almost an impossibility. We shall endeavor, however, to place the student in a position where he can figure out for himself the varying relation between these factors, and so arrive, with some practice, at his own conclusion.

For the production of a radiograph, either the static machine or the coil can be used.

As it is essential that the quantity of current behind the tube shall be considerable, it is necessary, except in taking pictures where only slight penetration is required, to use either a large static machine, *i. e.* one in which the quantity behind the discharge is considerable, or else the coil. A small static machine will give very satisfactory results in taking pictures of children and of extremities. Where we have our choice, however, a twelve or fifteen inch Rhomkoff coil is best for our purpose. With this, granting that our other factors are normal, pictures can be taken of any part of the body, after a certain amount of experience, which will reflect credit upon the operator.

The Interrupters.—When the coil is used, provided a small quantity of current only is required, as in extremities, either a mechanical or an electrolytic interrupter (either the Wehnault or Caldwell) can be used. For taking difficult pictures, the Wehnault interruper, with from fifteen to twenty-five ampères in the primary, is best for our purpose.

The Tube.—In the selection of a tube for radiographic work, we must look carefully to the focus. Unless our rays impinge upon the center of the anode, our picture will be blurred. This can be determined by the use of the fluoroscope, which should give not only good penetration, but absolute accuracy of definition. A high tube is best for our purpose. Indeed, it is essential to our success when deep pictures, such as hips, shoulders and stone in the kidney, are desired. The best focal distance for our tube is from fifteen to eighteen inches.

Regulation of the Tube.—It is essential to the success of a photograph that our self-regulating apparatus be accurately used. This can be determined by watching the ameter in the primary and observing the color in our tube. A careful manipulation of this apparatus will often prevent the breaking down of the vacuum in the tube.

When the vacuum begins to break, which will be noticed by the purpling of the color in the tube and also by a lower pitch in the sing of the spark gaps, the current should be instantly turned off. If this is not done, our vacuum will soon break down, making our tube useless. It should also be remembered that, after the vacuum begins to break, the tube is useless for further radiographic work at that sitting.

The Plates.—There are a number of makes of plates suitable for radiographic work. Most operators have an individual preference, but the essentials of a good plate are its freshness and its quickness. When it is possible, it is wise for the operator to buy the plates in small quantities and place them in the envelopes himself in a dark room. These plates are very sensitive to light, and should be placed in a thick lead-lined box, if they are carried through the sunlight, even, although wrapped in their outer envelopes, before being developed.

It goes without saying that the plates should not be exposed to the influence of the *x*-ray at any time except during the progress of the picture. However, operators often fail to realize the extent of the influence of the *x*-ray. I have personally had plates light-struck when placed in a heavy wooden box, separated from the tube by a wall, and twenty feet distant from the tube. When a picture is to be taken, the tube should be tried out, the patient placed in position, the focus determined, and then the plate brought in and placed in position. A detail worth observing is to place a coin in the upper right-hand corner of the plate. This will help us in determining the position of objects shown on the plate and often save us a good many puzzled moments.

The Patient.—Children are good radiographic subjects on account of the ease of penetration. In passing, we wish to call attention to the fact that the epiphyses of the various bones unite at varying periods in a child's life, some being delayed almost to maturity. We have frequently seen a fracture diagnosed by a good man, when the picture showed only the epiphysis united to the shaft by cartilage, the lesser density of the cartilage making it appear as though there were a separation. Children require relatively short exposures.

If we will keep in mind the law—the *x*-ray penetrates all substances with a velocity proportional to their density—and remember that fat is penetrated most readily, connective tissue next readily, and then, in order, cartilage, muscle, bone, blood, and, last of all, stone and metallic foreign bodies, we shall be able to determine, with our other factors normal, the proper exposure required in taking photographs of the different types of adults that come under our observation. Example: A fat man will be an easier subject for us than a muscular man of the same size. The muscles, containing much blood, tend to inhibit the rays. If we wish to make a photograph of a foreign body, a longer exposure, to differentiate properly, will be in order.

Radiographs of Fractures and Foreign Bodies.—We should never endeavor to diagnose a fracture or locate a foreign body by means of one radiograph. A little thought will show us how inaccurate will be a conclusion arrived at in this manner. Two or more photographs, in varying positions, should be taken, and the angle of incidence arrived at. This will give us the true location or position of the fracture or foreign body, gallstones, kidney stones, differentiation of bone lesions, etc.

For those who are more expert in radiography,

somewhat elaborate apparatus has been devised, by means of which steroscopic radiographs can be made. By following out the suggestions named above, however, accurate enough work for the average man can be done without resort to this procedure.

Personal Idiosyncrasy.—We must bear in mind that the susceptibility of subjects to the *x*-ray varies greatly. Using large amperage, as we do in these cases, and with a high tube, serious burns may often result from relatively short exposures. This fact should be constantly in our mind. The patient should be warned, that, while it is not probable, it is quite possible that a burn of considerable severity may result, especially if the radiograph is that of a deep part, and the operator should properly protect himself, by a written release, if possible, from the patient. It has not been our misfortune, in several years, to burn a patient, but too great care cannot be exercised.

Diaphragms and Compressional Apparatus.—When our radiograph embodies some deep-seated structure, such as the kidney, or when it is desirable to limit the chest or abdominal expansion, various forms of compressional apparatus, to which are attached the tube, have been invented. It is hardly possible to take good radiographs in these locations without some such aid.

Ferrotype Sheets.—These are sheets of thin, japanned iron, are commonly used, and can be obtained through any photographer. These are placed upon the table, the plate being placed upon them. Their object is to prevent the radiation of the rays, and so give us a clearer outline to our picture. They are a very desirable aid to good work.

Development of *X*-Ray Plates.—The developer used with skiagraphs varies with the exposure and character of picture taken. All *x*-ray plates of deep structures should be rocked continuously. If they are laid in the bath without rocking, a mottling of the plate may result. This rocking must be continued in some cases, even for twenty minutes or half an hour in the case of a slow developer, or where the exposure has not been properly timed. Attention to detail in development is nearly half the battle in obtaining good results.

Length of Exposure.—It is impossible to formulate a rule which will help us very much as to the length of time required to take radiographs. As will be seen, it depends upon too many factors; the quantity of current we are using, condition of the tube and of the plates, and the size and density of our patient. The larger the quantity of current, the higher the tube, and the less the density of our patient, the shorter will be the exposure. With our factors reversed, the exposure becomes much longer. Only individual experience will determine the ratio.

A note of warning should be sounded relative to the protection of the operator in taking radiographs. We must remember that here all our factors of harm are at their highest potential. The operator should stand behind a heavy lead-lined screen, or by an arrangement of switches, at a considerable distance from the tube, or, better still, in another room, with a lead-glass window through which he can observe the conditions. Evidences of disregard of this warning are constantly being brought to our attention, in the number of x-ray workers who are incapacitated by burns, atrophic skin, and neurasthenia, to say nothing of sterility and cancer, as the result of their carelessness.

137 West Sixty-ninth Street.

Vaginal Hemorrhage and Milky Secretion from the Mammæ in an Infant.—One case is reported by T. W. Dewar, who says that simultaneous occurrence of bloodless labor in the mother and of hemorrhagic vaginal discharge and milky secretion from both mammæ in the infant perhaps justifies report. Of course, no connection between the two is suggested. Labor set in in the mother at 2 P.M., and terminated at 10:30 P.M. A quarter of an hour after the placenta came away, the membranes intact, of a glistening pearly color. Neither before nor after birth, nor after expulsion of the placenta, was there any bleeding. Some hours after the lochia appeared and continued in amount and character in conformity with ordinary experience, the patient making a perfect recovery. It was her second child, a female, and weighed 6¼ pounds. Her first confinement was of the normal type. As regards the infant, a discharge of blood and mucus came from the vagina on the third day and lasted until the seventh. On the twelfth day the mammæ became hard, swollen, and tender, and the skin over both had an erythematous blush. From both a milky secretion exuded, and continued for three weeks. The left enlarged first, preceding the right by twenty-four hours. The excretion was aided morning and evening by gentle pressure and massage, and the tumefaction subdued without trouble. The child was not upset by it in any way.—*British Medical Journal.*

Phlebitis of the Leg After Laparotomy.—E. Mériel describes the signal-symptoms of phlebitis after laparotomy for tumors etc. as a rise of the pulse frequency that is not accompanied by a corresponding rise of temperature. The phlebitis begins about fifteen days after the operation when convalescence is beginning to be established. But this pulse has shown itself for some days, and perhaps from the day after the operation. It increases progressively in frequency without being small, as it is in peritonitis, and with it comes no typical rise of temperature for some time. Then there is a chill and a rise of temperature to 38.5° or 40°, with rise and fall each day, and then a return to apyrexia. This pulse depends on the obstruction produced by thromboses of the pelvic veins combined with a weak heart. Pain begins before the leg swells due to pressure on the veins by the connective tissue rings through which they pass. Embolism may result in sudden death like a clap of thunder out of a clear sky. The etiology consists of injuries to the veins of the pelvis or diseased conditions of these organs at or before the operation or changes in the blood which make it coagulate more easily than normal. Phlebitis never occurs in a normal vein.—*Gazette des Hôpitaux.*

Contribution to the Surgery of the Kidney.—Alessandri establishes the necessity of determining the function of the kidneys separately by separating the urine of the two organs in the bladder. To be absolutely certain of examining the urine of one kidney alone it is necessary to catheterize the two ureters. When this procedure is dangerous, as in cases of acute suppuration or tuberculosis, he prefers to catheterize the pathological kidney, using large sounds, so as to avoid the filtration of the urine about the catheter. Cryoscopy of the urine is as important as of the blood, in order to determine the actual condition of the kidneys. Cryoscopy of the blood appears to the author not to be of as much importance as has been represented. The author describes an interesting case of operation for interstitial nephritis in a patient who was anuric for eighteen days.—*La Riforma Medica.*

Syphilitic Fever.—Angelo Ceconi discusses the symptoms and diagnosis of syphilitic fever. The fever of tertiary syphilis occurs as it does in the secondary manifestations. It may be slight with a slight rise of temperature in the afternoon perhaps continuing into the night the rises being variable and changeable or the temperature may remain constantly elevated with an intermittent or remittent type and initial chills and sweating. It generally continues for weeks or months and is only affected by the action of mixed or iodide treatment under which it falls and disappears in a few days. It is not peculiar to any special tertiary lesion being found with localizations of the syphilitic virus in the nervous system, bones, articulations, serous membranes and lungs. It is observed frequently with liver lesions. It can be diagnosticated from typhoid and malaria only by careful serum tests and microscopic examinations of the blood. The spleen is enlarged in all three conditions. It is accompanied by headache and malaise, with some disturbance of the stomach. It occurs many years after the primary infection. Women seem to be more subject to it than men. It may continue for a long period without injuring the general health or decreasing the weight.—*La Riforma Medica.*

New York, May 1, 1909.

OPIUM SMOKING AND ITS PREVENTION AND CURE.

A STRONG anti-opium smoking movement is going on at the present time in the Far East, the home of the opium habit, and some reports containing the results of investigations on the subject have been published already. Before, however, referring to these, it may be mentioned as an interesting and somewhat curious fact that although the custom of smoking opium is most prevalent in Far Eastern countries and is generally regarded as originating in Asia, such is really not the case. It has been recently stated on good authority, that the practice of smoking the drug was introduced actually from Europe into Asia, where, needless to say, it has taken root and flourished exceedingly.

In 1907, a British commission, consisting of six members, was appointed to inquire into the consumption of opium in the Straits Settlements—a British possession— and in the Federated Malay States, which occupy the southern part of the Malay peninsula between the islands of Sumatra and Borneo. The report is most voluminous and it can be stated that the localities from which information was gained are most favorable to the gathering of instructive and accurate knowledge, as the inhabitants, especially those of the Federated States, are most addicted to the habit. A large proportion of the inhabitants of the Straits Settlements and of the Federated Malay States are Chinamen, and probably the custom of opium smoking in these places originated with the immigration of Chinese. The commissioners are of the opinion that the main reason for taking to the habit of smoking opium is the expression among the Chinese of the universal tendency of human nature to some form of narcotic indulgence.

With regard to the evils arising from the use of opium, the great majority of medical witnesses who gave evidence before the Commission expressed the view that opium smoking in moderation is relatively harmless and that even if the indulgence be carried to excess, there is no organic change in the body, but the disturbances are purely functional bad effects, such as constipation, disorders of the digestive organs, with emaciation and loss of energy. In the words of the report, "It appears, therefore, that in the opinion of those remarkably well qualified to judge opium smoking has little or no effect on the duration of life. That the evils arising from the use of opium are usually the subject of exaggeration and that the tendency of philanthropists to give undue prominence to bad cases and to generalize from the observation of them is undoubtedly a great factor in attributing to the use of opium more widely extended evils than really exist." In short, the expression, "evils of opium smoking," is applicable only to the case of "opium sots."

Opium smoking in Asia may be fairly compared to alcohol drinking in Europe and in other temperate and cold climates. And the evidence of medical witnesses before the Commission referred to above, bears a striking similarity to the evidence of many medical witnesses on the alcohol question. Despite the assertions of a large number of medical men of great scientific reputation that alcohol used under any conditions is useless and that generally its employment is harmful in the extreme, there are yet, perhaps, quite as large a number of physicians who hold that alcohol has its uses and that its evil effects are not nearly so great as its opponents attempt to prove. At any rate, Dr. Reid and others have argued very plausibly that a race which has been accustomed to the use of alcohol for generations acquires immunity to it, in a greater or less degree. This argument is also employed with respect to the consumption of opium by Far Eastern peoples, that they in a like manner have acquired a certain degree of immunity to the drug. The contention in both instances is true, but, of course, does not prove that the inhabitants of Europe and America would not be the better physically, mentally, and morally if alcohol were not drunk nor that the denizens of Asia would not benefit in mind, body, and soul if opium were placed beyond their reach.

At least, there is one point of agreement that abuse of either alcohol or opium is harmful and that any steps which tend to the restriction of the sale of these narcotics would be for the public good. Further, as it has been demonstrated conclusively that opium is very harmful to white persons, the importation of the drug into countries peopled by such should be carefully supervised. In this country, for example, where the opium habit is stated to be fairly prevalent in certain cities among members of the white race, all needful precautions should be taken. The importation of the drug, except for medicinal use, has now been forbidden, and it only remains to ensure the enforcement of the law.

As to the cure of the habit, the Commission did not appear to be very hopeful, for the report says: "The idea that stoppage of smoking in all ordinary cases in any way endangers life is exploded by the experience gained in cases of compulsory abstention in the prisons. Acute diarrhea has been noticed to be the result in some cases of compulsory deprivation, but on the whole there appears to be no ground for saying that in the instance of moderate smokers physical inconvenience more than purely ephemeral discomfort follows the cessation of the use of opium. We consider that in the cases

of smoking to excess cure by voluntary effort is a practical impossibility, and that subservience to opium in these somewhat isolated instances is to all intents and purposes final, but we think that with the requisite desire to break from its use the voluntary relinquishment of the opium habit is in the majority of cases possible."

The report touched upon in this article does not advance matters so far as our knowledge concerning the effects of opium on human beings is concerned. In many respects, it is crude and disappointing. The materials for an illuminating exposition of the opium question in the Far East seem to have been at hand, but were not taken advantage of. Especially from the scientific point of view is the report barren. The physicians examined declared for the most part that opium smoking in moderation was not injurious, but made no definite statements with regard to what constituted moderation or excess. There surely must be those who, while they cannot be denominated as "opium sots," yet smoke more than is good for them and who show more or less marked physiological effects. When a full report is published of the International Opium Commission, which began its session on February 1 under the presidency of Bishop Brent, it is to be anticipated and hoped that our knowledge of the subject from its physiological and scientific aspects will be greatly amplified.

CARBOLIC ACID GANGRENE.

Two observers writing from cities so remote from each other as St. Louis and Philadelphia have reported simultaneously five cases of gangrene following the use of carbolic acid as a surgical dressing. J. A. Kelly in the February number of *Annals of Surgery* reports a woman, aged 27, who applied a carbolic solution of unknown strength to a punctured wound of the finger. The dressing remained in place only five hours when intense pain brought about its removal. The finger was found to be dead and blackened from gangrene. The patient neglected advice of immediate amputation, but later consented to have the finger removed at the metatarsophalangeal joint. In the *St. Louis Medical Review*, also for February, W. E. Leighton cites four cases of carbolic acid gangrene of fingers and toes. He considers that two factors are productive of this untoward result of the use of carbolic acid: the skin becomes hardened and contracted by the application and hence produces mechanical constriction after the manner of a very tight bandage; or an artery, already sclerotic, in the affected digit offers poor resistance against local necrosis.

The faith possessed by the laity in carbolic acid as a disinfectant and germicide leads them very frequently into error. In the first place there are many drugs equally or more powerful as antiseptics which do not have the local anesthetic effect or disagreeable odor of phenol. This anesthetic effect of phenol is one of its greatest dangers, for it is likely that when pain following its use does begin in adjacent tissue, irreparable damage has already been done. However, the layman with an injured member, upon visiting a nearby drug store, either demands a carbolic solution, or, as quite often happens, is supplied with the drug by the pharmacist who speaks only of its poisonous constitutional effect and neglects to warn the patient concerning its local action.

There is, then, sufficient reason for limiting the sale of this drug to physicians exclusively, and for not allowing it to be dispensed to almost anyone who is willing to sign the "poison book." Most surgeons of experience have seen cases of carbolic gangrene caused either by the patient's ignorance, or, in a few cases, by failure on the part of the physician who first saw the case to remember what may happen. Moreover, it is not the strong but the weak percentages of the drug that may do damage. A finger has been lost through the use of a 10 per cent. carbolic ointment applied to an open wound, and a like result has followed the application of solutions 1 in 60 and 1 in 100 strength respectively. In most hospitals, especially in the dispensary service, carbolic acid is used chiefly for the sterilization of instruments which are washed in 95 per cent. alcohol and sterile water before use. Certainly in the light of past experience it is far safer to apply lead and opium, or alum acetate, or bichloride of mercury of suitable strength than to take chances with a drug so powerful in its local action as is phenol.

SCARLET FEVER.

Scarlet fever is a disease that appears annually in more or less severe epidemics, and therefore one with which every practitioner not a specialist should be familiar. Nevertheless, there is among physicians a lamentable unfamiliarity with some of the details of diagnosis and treatment. Many cases show a false membrane resembling that of diphtheria on the tonsils and pharynx, and in these cases a diagnosis of diphtheria complicating scarlatina is made. If a culture is made from such a throat it will often be found that there are no Klebs-Loeffler bacilli, but that the membranes contain streptococci. Since the true agent in the causation of scarlet fever has not been as yet isolated, we cannot say whether or not it is present in the membrane, but we must suppose it to be there, and may say that the streptococcus is an almost constant accompaniment of scarlet fever.

In the *Gazette des Hôpitaux* for February 13 and 20, 1909, L. Babonneix and M. Brelot give a careful study of the various forms of angina found in scarlet fever. The ordinary sore throat of pure scarlet fever is a slight affair, but it is often complicated with a severe mixed infection and swelling of the lymphatic glands. This may become pseudomembranous, ulcerative, or even gangrenous, and may appear at any stage of the disease, even during convalescence. The severity of the general symptoms is greatly increased by any one of these severe anginas, and some of them are rapidly fatal, with immense swellings of the neck. The gangrenous forms and true Klebs-Loeffler diphtheria com-

plicating scarlet fever are confined to hospitals, where the little patients, coming from bad surroundings, are exposed to the infection of diphtheria. True diphtheria is found generally in the convalescent stage only. Recognizing these facts, cleansing the nose and throat frequently with a disinfecting solution becomes of great importance both to the patient and to those around him.

Sudden death may occur at any period of scarlet fever in children or adults without any apparent cause. This is well brought out by A. Gouget and Dechaux, in the *Presse Médicale* of February 24, 1909. It may come very early, before diagnosis is possible or the rash has appeared, being preceded by convulsions; or it may come heralded by no unfavorable symptom except a thready, rapid pulse. It is quite frequent in the nephritic period of the disease. Autopsy seldom gives light in any of these cases on the cause of death. It seems to result from an overwhelming nerve poisoning.

P. Gallois, writing in the *Bulletin Médical* of February 20, 1909, calls scarlet fever an ordinary angina with a secondary eruption. The angina becomes serious only when it is complicated by streptococcus infection. The eruption is not important. Hence prophylactic measures should accompany every angina, whether accompanied by eruption or not. Isolation becomes unnecessary after the patient has recovered from his angina, and keeping him isolated until desquamation is complete, Gallois maintains, is not only useless, but oppressive, since this desquamation is not the carrier of the disease, but the secretions from the throat are the dangerous part of it. Whether this be the true view or no, if we are to detect desquamation as long as it exists, we must not fail to examine the feet of the patient before pronouncing him clean, since the process of desquamation continues on the soles of the feet long after the body is free from scales.

The Increase of Antitrypsin in the Blood.

It has been known for a long time that the blood of healthy animals, including man, possesses feeble antitryptic properties. Recently, Brieger and Trevinq have utilized this fact in the study of the blood of patients suffering from malignant disease and from other conditions leading to cachexia, and have discovered the important fact that the amount of antitrypsin in the blood is very much increased in these conditions. Indeed, the reaction was so frequently obtained in cachexia of malignant disease, that these authors thought of the possibility of using this fact in the differential diagnosis of such disease. Other publications soon showed, however, that the application of such a diagnostic measure was very limited, the increase in antitrypsin being, perhaps, specific for cachexia, but not necessarily for malignant disease. Thus Braunstein, writing in the *Deutsche medizinische Wochenschrift* for April 1, 1909, reports increase in antitrypsin in 25 per cent. of cases of cachexia, caused by nonmalignant disease. On the other hand, in cases of carcinoma the increase in antitrypsin was noted in over 91 per cent. of cases, so that a certain diagnostic value is certainly possessed by this reaction. Braunstein has occupied himself with the nature of the causes which lead to the increase of antitryptic properties of the blood, and has studied the reaction in animals in whom a cachectic condition was produced by the administration of phloridzin and phosphorus. The blood of such animals showed distinct increase in antitrypsin, and as the cachexia produced by these substances is due to a greatly increased destruction of proteids, Braunstein concludes that the reaction in cachectic human beings is likewise caused by the same disturbance of metabolism. He concludes that the increase in antitrypsin is no more specific for malignant disease than the presence of lactic acid in the gastric contents; normal amounts, however, speak strongly against the existence of such disease, a fact which may prove of value in differentiating benign from malignant tumors.

News of the Week.

Health Report of the Canal Zone.—The report of Dr. William C. Gorgas, chief sanitary officer, for the month of February, 1909, calls attention to the fact that the death rate among employees for that month, 10.98, is lower than that for any February since the work on the isthmus was begun. In 1906, the rate for the month of February was 43 per thousand; in 1907, 25.62; in 1908, 12.72. The same decrease for the month is noted in the death rate for the total population, the figures being, 1906, 38.09 per thousand; 1907, 36.07; 1908, 21.40; and 1909, 18.59. There was also a large decrease in the amount of sickness among the employees during February as compared with January. During the latter month the average sick among the employees every day was 1,116 men; during February this average was reduced to 951. During January, 1,258 cases of malaria among employees were admitted to the hospitals; during February, only 852. No case of yellow fever, plague, or smallpox occurred on the isthmus during the month.

United States Pharmacopeial Convention.—In accordance with the provisions of the by-laws of the convention, the president, Dr. Horatio C. Wood, has invited the several bodies, entitled under the constitution to representation, to appoint delegates to the First Decennial meeting of the Ninth Decennial Convention for the Revision of the Pharmacopeia of the United States of America, to be held in Washington, on May 10, 1909. Notification of the appointment of delegates, accompanied by the necessary certification of eligibility, should be forwarded as soon as possible to the Secretary of the Board of Trustees, Dr. Murray G. Motter, 1841 Summit Place, Washington, D. C. Incorporated medical colleges and medical schools connected with incorporated universities or colleges; incorporated colleges of pharmacy; incorporated State Medical Associations and Pharmaceutical Associations; the American Medical Association; the American Pharmaceutical Association; and the American Chemical Society, all are entitled to representation at the convention.

The University and Bellevue Hospital Medical College.—Mr. Andrew Carnegie has given $75,000 to enlarge the Carnegie Medical Laboratory of this college, the gift being in honor of the successful work in bacteriology and pathology in the laboratory during the last twenty-five years. Announcement is made also of a gift of $2,000 by the widow and

daughters of Dr. Glover C. Arnold to establish the Glover C. Arnold surgery prize, the annual income of the fund to be awarded each year to the member of the graduating class of the University and Bellevue Hospital Medical College who shall stand the highest in surgery.

The Neurological Institute of New York, a hospital and clinic for the treatment of nervous and mental diseases, was incorporated by order of the Supreme Court on April 21. The incorporators include Dr. Joseph Collins, Dr. Joseph Frankel, Otto H. Kahn, Adrian Iselin, Jr., Richard Watson Gilder, and others. The prospectus of the institute sets forth that "the real reason why such forms of supernaturalism as Christian Science, New Thought, the Emmanuel Movement, and others, have obtained such a hold on the people of this country and such a popularity in this and neighboring communities is due more largely to the fact that physicians are untrained in the recognition of so-called functional and nervous metal diseases, and unaccustomed to the proper and successful treatment of them, than to all other causes combined."

Appointments at the Rockefeller Institute.—At a meeting of the Board of Directors of the Rockefeller Institute for Medical Research, held on April 10, the following promotions and appointments were made: *Associate Members*, John Auer (Physiology), Hideyo Noguchi (Pathology), Alexis Carrel (Surgery); *Associate*, George W. Heimrod (Chemistry); *Assistants*, Martha Wallstein (Pathology), Richard V. Lamar (Pathology), A. O. Shaklee (Physiology), Gustave M. Meyer (Chemistry); *Fellows*, M. T. Burrows (Pathology), Paul F. Clark (Bacteriology).

Death Rate High.—Largely because of the prevalence of pneumonia, the death rate in New York for the week ending April 17, was higher than that for the corresponding week of last year, the figures being 19.48 as compared to 18.21. The deaths from pneumonia numbered 359, the total number of deaths for the week being 1,705, or 161 more than the same week in 1908.

Cattle Quarantine Removed.—Secretary Wilson on April 20 issued an order removing completely the quarantine which he proclaimed last November on account of the prevalence of the foot and mouth disease among cattle. It has been determined that the disease does not now exist in the United States. It is estimated that about $1,000,000 was spent in eradicating the disease, of which more than half was paid out by the Federal Government.

Fire in Hospital.—A fire which started in the boiler room of the Peekskill Hospital, on the morning of April 21, compelled the removal of the twenty-three patients in the institution to the nurses' home and the isolation pavilion near by. Under the direction of the superintendent, the nurses accomplished the transfer quietly and without accident.

Rockaway Park Sanitarium.—The directors of the Rockaway Park Sanitarium for Hebrew Children announce that their buildings have been enlarged so as to permit of the addition of sixty beds, making a total number of 475 beds. It is estimated that between 25,000 and 30,000 children will during the coming summer have the benefits of the all-day outings on the water and a short stay at the sanitarium.

The American Gynecological Society held its annual dinner, on April 22, at the Waldorf-Astoria, New York. The dinner commemorated the first operation of ovariotomy performed by Dr. Ephraim McDowell of Dansville, Ky.

Asylum Plan Changed.—Because of the opposition among the residents of the neighborhood to the location of the Long Island State Hospital for the Insane at Greenvale, the State Commission in Lunacy has abandoned that site, and will attempt to obtain land near Hicksville, it is understood.

The New York Institution for the Blind has purchased a site for its new buildings in Bronxville. About fifty-one acres have been acquired, and the present quarters at Ninth avenue and Thirty-fourth street will be abandoned and the property sold as soon as the new home is ready.

Compulsory Vaccination.—At a recent meeting of the Chicago Medical Society, compulsory vaccination was favored as being in keeping with the present advanced position of preventive medicine. The resolutions were introduced by Dr. William L. Baum in support of a bill making vaccination compulsory that is pending before the Legislature.

Chicago Milk.—Commissioner of Health, Dr. William A. Evans, Chicago, recently asserted before the City Club, that the work accomplished in Chicago in the last six months to protect the city's milk supply was greater than had ever been done in any other city in the same length of time. Chicago gets milk from twelve thousand farms in four States. The conditions on these farms are known, and if one desires he may find out under just what conditions the milk the people are using is produced.

The Federation of Labor and Tuberculosis.—The Illinois State Federation of Labor has decided to begin an active fight, with a view to stamping out tuberculosis. Literature, which deals with occupational diseases, and more especially with tuberculosis, giving full information with regard to the symptoms of the disease, and the work that is being done for its eradication, will be distributed by the Federation among 500,000 members of the union.

Tuberculosis Camp.—The Lowell General Hospital will open its tuberculosis camp for its fourth season, on May 3. The camp has accommodations for twelve men and sixteen women. It will remain open throughout the summer.

American Medical Editors' Association.—The coming meeting of this association, which will be held at the Marlborough-Blenheim, Atlantic City, will celebrate the fortieth anniversary, and a good program has been prepared for the occasion. It is expected that delegates from the foreign medical press will be present, and it is hoped that every medical editor will make an effort to be present at the meetings.

The Ohio State Medical Association.—In response to the invitation of the Academy of Medicine of Cincinnati, the Ohio State Medical Association will meet in that city on May 5, 6, and 7. On the evening of the first day a smoker will be held, and on the evening of the second the annual banquet. The headquarters for the meetings will be at the Hotel Sinton.

The Iowa State Medical Society will hold its annual meeting in Dubuque on May 19, 20, and 21. On the preceding day the State Society of Medical Women will meet.

The Southwest Missouri Medical Society will meet in Springfield, on May 6 and 7, under the presidency of Dr. W. P. Patterson.

The Belknap County (N. H.) Medical Society held its annual meeting on April 12 and elected the following officers for the ensuing year: *President*, Dr. E. P. Hodgden; *Vice-President*, Dr. F. B. Easton; *Secretary and Treasurer*, Dr. A. H. Harriman; *Executive Committee*, Dr. A. W. Abbott, Dr. W. H. True and Dr. E. F. Houghton of Tilton; *Counsellors*, Dr. G. H. Saltmarsh, Dr. J. G. Quinby and Dr. John Huckins of Ashland.

The Florida Medical Association, at its annual meeting in Pensacola on April 8, elected the following officers: *President*, Dr. H. E. Palmer of Tallahassee; *Vice-Presidents*, Dr. C. P. Rogers of Jacksonville and Dr. W. S. Bird of Tampa.

The Windham County (Conn.) Medical Society held its one hundred and sixteenth annual meeting on April 15, at Putnam. The following were elected officers for the ensuing year: *President*, John Weldon, Willimantic; *Vice-President*, George M. Burroughs, Danielson; *Secretary and Treasurer*, James L. Gardner, Central Village; *Counselor*, J. B. Kent, Putnam; *Delegates to State Convention*, C. C. Gildersleeve, Woodstock; R. C. White, Willimantic.

The Tennessee State Medical Society met at Nashville on April 14. Officers for the ensuing year were elected as follows: *President*, Dr. Jere L. Crook of Jackson; *Vice-Presidents*, from East Tennessee, Dr. C. H. Davis of Knoxville; from West Tennessee, Dr. O. Dulaney of Dyersburg; from Middle Tennessee, Dr. T. J. Coble of Shelbyville; *Secretary*, Dr. George H. Price of Davidson County; *Delegate to the American Medical Association*, Dr. L. A. Garbrough of Covington.

The Fairfield County (Conn.) Medical Association, at its one hundred and seventeenth annual meeting, on April 13, at Norwalk, elected the following officers: *President*, Dr. Samuel Pierson, Stamford; *Vice-President*, H. E. Smythe, M.D., of Bridgeport; *Secretary*, Frank W. Stevens, M.D., Bridgeport; *Treasurer*, James Douglass Gold of Bridgeport; *Counselor*, S. M. Garlick, M.D., of Bridgeport; *Censors*, William S. Randell, M.D., Edward M. Smith, M.D., and D. C. Brown, M.D.

Obituary Notes.—Dr. Frank W. Draper, for twenty-eight years medical examiner of Suffolk County, Mass., and for thirty-five years on the staff of the Harvard Medical School, died of pneumonia, at his home in Brookline on April 19, aged 66 years. Dr. Draper was graduated from Brown University in 1862, and from the Harvard Medical School in 1869. During the Civil War he enlisted as a private in the 35th Massachusetts Volunteer Infantry, and was later promoted to a captaincy. He was at various times visiting physician to the Boston City Hospital, editor of the Massachusetts Registration Reports, assistant editor of the *Boston Medical and Surgical Journal*, and lecturer on forensic medicine, assistant professor, and, at the time of his death, professor of legal medicine in the Harvard Medical School. He was a member of the Massachusetts Medical Society, of which he was president for 1900-1902, the American Public Health Association, and the American Statistical Association, and a fellow of the American Association of Arts and Sciences. He was the author of a well known text-book on legal medicine.

Dr. John E. W. Sanderson of New York died at his home of heart disease on April 10. He was a graduate of Amherst College and of the College of Physicians and Surgeons, New York, from which he received his medical degree in 1886. Dr. Sanderson was at one time on the staffs of St. Mary's and the Eastern District Hospitals of Brooklyn.

Dr. Charles E. Lancaster of Brunswick, Me., died on April 5, following injuries which he received when thrown from his carriage about three weeks ago. Dr. Lancaster was born in 1862, and was graduated from Bowdoin Medical College in 1888.

Dr. Charles Appleton Packard of Bath, Me., died at his home on April 6, aged 80 years. Dr. Packard was graduated from Bowdoin Medical College in 1856. He was a member of the Maine Medical Society and of the Bath Medical Society, and for twenty years was physician to the Military and Naval Orphan Asylum.

Dr. J. P. Bone of Arlington, Tenn., died at his home, on April 11, after a short illness, aged 78 years. Dr. Bone was graduated from the Louisville Medical College in 1860.

Dr. A. D. Scruggs of Knoxville, Tenn., died at his home, after a long illness, on April 9, aged 67 years. He was graduated from the Jefferson Medical College at Philadelphia in 1867.

Dr. John C. Dwyer of Ansonia, Conn., died at his home, on April 13, of valvular disease of the heart, aged 31 years. Dr. Dwyer was graduated from the College of Physicians and Surgeons of Baltimore, Md., in 1900, and for a time served as resident physician at the Maryland Lying-In Hospital.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

TREATMENT OF SCHOOL CHILDREN'S DISEASES—GRADUATED LABOR IN PHTHISIS—SLEEPING SICKNESS EXPEDITIONS—ROYAL COLLEGE OF PHYSICIANS AND CAIUS COLLEGE—ROYAL COLLEGE OF SURGEONS AND MIDWIVES' BOARD—OBITUARY.

London, April 9, 1909.

The London County Council has of late been a good deal exercised as to medical inspection of the school children, and further as to the question of treatment. The Education Committee has seemed at times to have no consideration as to the cost of anything proposed and the ratepayers are being roused to opposition The Prime Minister has refused an application for help from the Imperial Exchequer toward the cost of school clinics or other mode of treating school children's diseases. The Finance Committee accordingly reports in presence of such proposals that the medical treatment, like the feeding of the children, is optional, not compulsory, on the Council, and that the Council should itself settle the general question. A subsidiary question is whether the Council should be empowered to recover the cost from parents. The burden of the education rate is rising and appears certain to continue to rise in face of automatic increase in teachers' salaries, provision of meals, medical inspection, and other expenses to which the Council is committed. Moreover, demands are being raised for further expenditure in all directions. The teachers, having been trained at the public expense and given an occupation above what they could otherwise have reached, are asking for higher wages, superannuation, and less work. Like the daughters of the horse-leech, they cry continually "more, more." With regard to the way in which medical treatment could be provided, I have in a former letter referred to the question of school clinics or the utilization of hospitals and dispensaries. I may add that some of the Councilors think that benefit societies would perhaps work with them. The chairman of the Education Committee urged the Council to lead the van by taking in hand first of all diseases which hindered the children's progress, such as ringworm, defects of sight, and ear discharges. But he

was considerate enough to say that he would not at present propose to impose on the rates the enormous cost of dealing with defective teeth. Evidently he hopes to do so if he can get the power to make the parents repay. But experience should teach him that the recovery of such cost is practically hopeless. It was urged that the expense incurred by inspection would be wasted unless followed up by treatment. Obviously it is time to call a halt in the course of taking up all the responsibilities of parents and there is a movement in favor of doing this and further of enforcing on parents their primary duties to their offspring. But how? As to medical treatment, the most popular plan seems to be to concentrate the work in a few medical officers and indirectly ruin the rest of the profession. And the mass of the profession is apathetic, just as it was when it suffered an inferior order, the midwives, to absorb much of its income and is now crying out at the loss. This outcry it met by the meeting of an association last week to promote the training of more midwives, when the chairman declared their movement would benefit rather than militate against the pecuniary interests of medical practitioners!

To return to the Council, I should add that after a prolonged discussion at the adjourned meeting on Tuesday the question was referred back to the Education Committee to report as to the estimated cost of treating the diseases referred to (ring-worm and affections of the ears, eyes, teeth, etc.), as to the degree to which they affect the educational efficiency of the schools, and as to the steps to be taken to enable the local school authorities to recover the cost of treatment from parents who are in a position to pay for it.

Unusual interest attaches to the annual meeting of the Royal National Hospital for Consumption at Ventnor, which was held in London on Tuesday. The Earl of Roseberry presided and in receiving the report referred to the just claim of the hospital to a substantial share of the King's Hospital Fund, but as his Lordship is one of the managing council he could not say much about that, but in the capacity of president of this hospital, which received patients from every part of England and some from London, he did think they had a claim on that fund and he hoped it might be possible for the case to be reconsidered. He then referred to the trial which had been made in the hospital of the graduated labor treatment, which had been applied to some fifty patients and with most satisfactory results, both as regarded their strength and their moral cheerfulness. The system involved a residence somewhat more prolonged than that of the other patients, but the results had been so satisfactory that its continuance was justified. Lord Roseberry then pointed out this was a curative institution and as such deserved help from the nation as a whole, and he asked those great railway companies and firms employing a large number of men who constantly sought admission to consider whether it would not be more in accordance with their dignity and duty if they became regular subscribers to a hospital which thus benefited them.

Dr. Robertson then gave some account of the experiment in the treatment by graduated labor. The work of the scheme began, he said, by keeping three test patients from five to seven months. Including these men, there had been discharged from the hospital 37 men and 19 women who were selected for a prolonged course of treatment. Of these, 40 left in full working capacity, 10 in partial working capacity, and all were still at work, living their ordinary life. Six patients proved unsuitable or did not do well. Of the 56 patients, 18 had no definite physical signs of disease in their chests when they left, and many of the others showed striking improvement in that respect. He claimed for the treatment that patients were able to return to the work in which they had been previously employed and so to maintain themselves. Experience had shown that to limit the time of treatment was disastrous. Patients who had benefited in the hospital under older plans of treatment had often broken down again immediately after leaving. They had simply benefited by the fresh air, rest, and good diet, but on resuming their physical work were unfitted for it.

Dr. Robertson spoiled the effect of his speech by suggesting that the Local Government Board might undertake, not only the treatment of consumptives, but the maintenance of their wives and families—a proposal so far ahead of the most ardent Socialist that the audience evidently regarded it as absurd. It certainly gives cloak to the contemptuous sneer of some that "medical enthusiasts are never practical." The chairman, in replying to a vote of thanks, remarked that he would not care to face the responsibility of supporting the families of invalids as well as the cost of armaments.

The eighteenth expedition of the Liverpool Tropical School, sent to Central Africa to investigate sleeping sickness, have just returned, after a sojourn of about two years, during which they covered about 9,000 miles on foot, principally in Nyassaland and Northeastern Rhodesia. They report that in high latitudes the health of Europeans is usually good if proper precautions be taken to avoid malaria, dysentery, and tick fever. The tsetse fly has a very wide distribution and renders a large part of the territory practically useless. On the other hand, the glossina is much more circumscribed. They found it on the Luapula River, on Lakes Merwer and Takanyika, and some of their affluents, but did not meet with it in Nyassaland. Cases of sleeping sickness were found near these lakes and the report states that the Chartered Company's officials are vigorously working against the fly. In reference to distribution, I may cite an interesting report of Captain Ensor to the Sudan Sleeping Sickness Commission. He says *Glossina palpalis* and *Glossina morsitans* appear to occupy different spheres and never encroach on each other's hunting grounds. *G. palpalis* is named by the Arabs "Diban el Marad en Noom," which means the fly of the sleeping sickness, while *G. morsitans* is called "Diban el Marad el Bohim," or the fly of the cattle disease. *G. palpalis*, which is generally credited as the chief if not only carrier of human trypanosomes, is much less persistent than *G. morsitans*, which is such a greedy blood-sucker that it will follow a man into the area of *G. palpalis*, but will then almost immediately leave him to the regular occupants of that area.

At a meeting of Fellows of the Royal College of Physicians on Monday Sir Richard Douglas Powell was reelected president for the ensuing year. It was announced that next year will be the 400th anniversary of the birth of Dr. Caius, who in his time was president of the college. On the proposal of Dr. Payne it was resolved to cooperate with Caius College, Cambridge, in reprinting the works of Dr. Caius to commemorate the occasion.

The president delivered his annual address, in which he referred to the events of the year and gave obituary notes of ten Fellows who had died during that time, and of whose deaths I informed you as they occurred.

At the quarterly meeting of the Council of the Royal College of Surgeons Dr. R. T. Leiper of the London School of Tropical Medicine was appointed to revise and renovate the collection of entozoa in the Hunterian Museum.

The Jacksonian prize was awarded to Mr. Lockhart Mummery for his essay on diseases of the colon removable by operation, and the subject for the next prize was fixed as tuberculous disease of the urinary bladder and male genital organs. The annual report of the representative on the Midwives' Board, Dr. Ward Cousins, was presented, which stated that the deaths in childbirth had not diminished since the Act came into operation (April, 1903); that no guarantee exists for paying medical practitioners called in to assist midwives in difficult cases, and that consequently there is serious trouble in all parts of the country. It is hoped, when the whole details have been submitted to the committee appointed by the Government to inquire into the matter, the defects will be removed.

The death has occurred of Lt.-Col. A. O. Geoghegan, M.D., late of the R. A. M. C. Educated in Dublin and at Queen's College, Galway, he graduated at the Royal University, M.D. 1878 and M.Ch. the next year. He entered the Army Medical Service in 1880, and served in the Nile expedition in 1898, receiving the Egyptian as well as the Khedive's medal. He retired in 1907.

Death has also removed Dr. Thomas Crawford Hayes from the consulting staff of King's College Hospital. Educated at Trinity College, Dublin, he took the M.A. there with the gold medal. He came to King's and qualified L.S.A. in 1870. He took M.R.C.P. in 1872 and was elected to the Fellowship in 1889, having in the meantime become professor of obstetrics and gynecology in the college and physician accoucheur to the hospital. He had served as physician to the General Lying-in Hospital and as examiner in midwifery on the Conjoint Board.

OUR PARIS LETTER.

(From Our Regular Correspondent.)

CALCULUS OF THE KIDNEY AND URETER—SOLUBLE SILVER—TREATMENT OF OBESITY—TREATMENT OF SYPHILIS—TINCTURE OF IODINE FOR SKIN DISINFECTION.

PARIS, April 15, 1909.

At a meeting of the Society of Internal Medicine, Doyen presented an interesting case of calculus of the kidney and right ureter. The diagnosis was confirmed both by radiography, which showed the presence of two calculi, one in the pelvis of the kidney and one in the ureter, and by direct exploration made by himself. By means of his direct-vision cystoscope he was able to catheterize the right ureter, which allowed it to be seen that there was insufficient function of the right kidney, while the left kidney excreted a large amount of urine, very rich in extractives. Nephroureterectomy was practised with a very long lumbar incision, which permitted the removal of the two calculi, one from the pelvis and one which obstructed the ureter. The patient made a complete recovery. The extirpated kidney had very little parenchymal tissue remaining; there was a typical pyonephrosis from calculi.

Netter read a paper on the use of colloidal silver in therapeutics. After giving empirical facts, the results of the work of Credé and Halstedt, he stated that the cases in which he had obtained the most remarkable results were those of puerperal infection, subacute otitis, pyemia following furuncles, ulcerative endocarditis, and severe dysentery. In the last-named disease the remedy was given internally and in enemata. In severe cases intravenous injections are necessary. The author considers this method absolutely without danger.

Marcel Labbé read an interesting paper on the treatment of obesity. He believes that there is only one method of treatment: we must decrease the alimentary income and increase the expenditure of energy. Obesity may be produced in two ways: by the increase of ingesta, obesity of great eaters; by diminution of expenditure, the obesity of the sedentary life. The reduction of the alimentary régime is difficult to obtain when the patient cannot be made to change his habits. This is what causes the success of mineral springs, such as Brides and Marienbad, where the patient is submitted to a rigorous alimentary discipline. Among the foods that must be reduced and even suppressed are, first of all, the fats, bread, pastries, and sweets; salt ought also to be lessened as much as possible. The number of meals matters little; it is better to eat little and often, so as to calm the pangs of hunger, than much and infrequently. One of the most frequent of lay methods is to stop drinking. This is an important error, which may even become dangerous, for if the absence of water in the organism seems to lessen the weight by simple dehydration of the tissues, this produces troubles which may be very prejudicial to the work of the kidneys. In reduction by means of exercise, the latter should be dosed like a medicine; walking is especially to be recommended, whether on level ground or up-hill. It has a double advantage, for while it lessens the fat, it increases the muscular tissue through active function. The treatment of obesity by medicine should be absolutely given up, for it is injurious. The thyroid body, the use of which in obesity has been lauded, is extremely dangerous; taken in small doses it has no effect at all, absorbed in large doses it is a poison, and some cases of death are to be imputed to it; its action is very prejudicial because it acts not upon the fats, but upon the muscles, destroying the latter and respecting the former.

Leredde presented a communication on the treatment of syphilis. Intensive mercurial treatment should be defined precisely taking account of the amount of mercury introduced into the organism. The maximum dose is 0.03 (gr. ½) per day, and this can be borne by only a few individuals. The dose of 0.02 (gr. 1/3) per day is borne by almost all vigorous adults. This constitutes the minimum dose for intensive treatment. Leredde states that not all the mercurial salts have the same amount of mercury in them; for example, the biniodide contains 44 per cent. and the bichloride 73 per cent. The intensive treatment should be used: (1) At the beginning of the disease, with the roseola; (2) in case of cutaneous or mucous syphilis, visible externally, and not curable by the ordinary treatment; (3) in visceral and nervous syphilis, tabes and general paralysis; (4) when a diagnosis must be established.

At a late meeting of the Surgical Society the topic of study was disinfection of the skin by tincture of iodine. Walther, to prove the value of this treatment of disinfection of the skin, has had fragments from incisions into the skin examined microscopically. It was shown by these experiments that the iodine had penetrated deeply into the thickness of the epidermis and superficial portions of the derma. Before applying the tincture of iodine he always covers the skin with a compress soaked in ether in order to increase the penetration of the iodine. He believes that less than five minutes after the application of the iodine the skin asepsis is nearly complete, but it requires a certain time for the microbes to be destroyed; still, after ten minutes the sterilization of the skin is always perfect. The previous soaping of the skin interferes with impregnation of the skin by the tincture of iodine. When the iodine is applied alone it penetrates into the deeper parts of the skin and exercises a marked influence on the microbes contained therein. Guinard said that tincture of iodine had been employed for many years by surgeons, but that it was questionable whether a simple application of this substance would give real security from the point of view of asepsis. Pierre Delbet and Quenu had made use of tincture of iodine after washing the skin with soap, ether, and alcohol. Rouchard, Routier, and Réclus believed that the application of tincture of iodine directly on the skin, without any previous preparation, effected an economy of time which should be taken into consideration, and might be of service. Routier operated in this way in a case of extrauterine pregnancy which had ruptured, in which a simple painting of iodine on the skin enabled him to gain time, and allowed him to omit scrubbing the abdomen, which would certainly have increased the liability to hemorrhage.

CIVILIAN PHYSICIANS VS. ARMY SURGEONS IN MILITARY CASES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Among the many difficulties the army surgeon has to encounter (and I imagine the same applies to our brothers of the navy) one of the most annoying is the ease with which civilian physicians are induced to give opinions in rebuttal of the official-professional opinion of the military surgeon. This takes the form of certificates, either to the effect that an applicant for admission to the service, or an officer, or enlisted man found physically imperfect by the medical officer, and rejected on that account, is perfectly sound in every respect; or that an officer, reported well enough to do his duty, is, in the civilian physician's opinion, a physical wreck.

These opinions are so freely given, and, as a rule, so neatly fit the wishes of the applicant for the civilian physician's examination and opinion, that they no longer have any official value at all in deciding these cases, and are entirely overlooked, no matter how distinguished a name is subscribed to them. Let me give an illustration: An applicant for appointment to West Point has been found physically disqualified, by reason of defective vision; this rejected applicant secures the services of an obliging friend of about the same age, whose vision is known to be perfect. This substitute reports to some well-known ophthalmologist, giving the name of the rejected applicant, and is given by the civilian oculist a clean bill of health. This paper is passed over to the rejected candidate and, armed with it, some political friend demands the reversal of the medical officer's opinion, and another cripple is added to the army list. Or per contra, an officer, already in the service, sees ahead of him an examination for promotion, which he knows he cannot pass. His only hope is to be retired. Army surgeons examine him, find nothing wrong, and so report. He gets a leave, applies to some prominent neurologist, gives details of a long list of purely subjective symptoms, the neurologist believes him, and he is given a certificate to the effect that he suffers from "neurasthenia." I know of one such case, where the opinion given was from a very distinguished authority, but he was, when the matter was explained to him, perfectly willing to admit that his diagnosis was made entirely on the officer's own statements, under the supposition that an officer would not tell him what was not true. I am sorry to say that there is a small proportion of officers who will not hesitate to deceive a physician under these circumstances. To compel this man to undergo his examination was a very difficult and tedious matter. He failed, as was to be expected, and was wholly retired, but that carelessly given opinion made an enormous amount of trouble for the surgeons on the promotion board. It almost seems that many civilian phy-

sicians will give any opinion they are paid to give, and decide cases entirely according to the applicant's wishes.

The medical officer in these cases has a double duty to perform. He must see that the applicant for admission, or the officer or enlisted man already in the service, gets justice, but he must also protect the Government against fraud, and do his best to keep the retired and the pension lists from being crowded with healthy men. He stands, too, as a barrier against the admission into the service of men physically unfit for it. Unfortunately officers of the line who are members of these promotion and retiring boards, and who have a vote in deciding the outcome, seeing a certificate from an authority so well known that even the laity recognizes his name, are liable to give undue weight to these opinions, which may have been given after examination of a healthy impersonator in one case or an afflicted one in another.

It is very rare indeed that one of these applicants for an opinion gets one that he does not want, *i.e.* if he wants to get in he is pronounced sound; if he wants to get out he is certified to be a physical wreck. I have personally had a refreshing experience of an honest civilian doctor, who, when applied to by an officer whom I had reported fit for duty, examined him very carefully, pronounced him "in robust health fit for duty in any climate" (this officer was particularly anxious not to go to the Philippines), demanded and secured fifty dollars for his opinion. But this case was so rare that it stands almost alone. Certainly it is the only one in my experience (and I have been in the service twenty-eight years) where a civilian physician gave an opinion at variance with the wishes of the applicant for physical examination.

The medical officer in these cases is absolutely disinterested. His tendency is to give the man examined the benefit of any doubt there may be in the case, but he is also, if he does his duty, fully aware of his obligation to the Government that employs him. His experience as an examiner of recruits and his knowledge of what is required of officers and men fit him better than the average civilian doctor to decide whether a man is or is not fit for active military duty.

The civilian physician, on the other hand, is naturally ignorant of the motives that may actuate an applicant for examination, knows nothing of the duties required of him, and ought to be very chary of expressing an opinion under the circumstances. The rule is the other way, and in nine cases out of ten the civilian physician, without hesitation, gives opinions entirely at variance with those expressed officially by the medical officer, trained and experienced in dealing with such cases, and making his statement under oath. Besides this, while the medical officer can establish without difficulty the identity of the man examined, the civil surgeon has no such assurance.

W. H. Arthur,
Lieutenant-Colonel, Medical Corps, U. S. Army.

A WORD FOR THE OUTCAST.

To the Editor of the Medical Record:

Sir:—It would appear, judging from the action of some municipal health officers and medical boards, from the general disinclination of the public press to express any doubt as to the wisdom or necessity of the complete segregation of the leper, and from the barbaric and inhuman treatment to which he is frequently subjected, that the feebly contagious character of leprosy is practically unrecognized here. In Europe, Asia, and Africa generally segregation is not compulsory, and no law interferes with the personal liberty of the sufferer from the disease. In good hygienic and sanitary conditions it is proven to be unnecessary, in endemic centers practically impossible, and as a prophylactic measure ineffectual, as shown in the Hawaiian experience. In Norway complete segregation of the lepers has never been enforced either before or since the Segregation Act of 1885. In Bergen, at the writer's visit before 1885, the lepers entered the hospitals and asylums as they pleased; and in the milder forms of the disease were permitted to work and freely visit and vend their wares in the open market and upon the streets. Tourists often visited the hospitals as one of the sights of the town. As late as 1889, four years after the passage of the so-called Segregation Act, a correspondent of the *Lancet* reports the same practice as existing, and to-day, on their way to the asylums at Bergen, Throndhjem, and Molde, lepers are permitted to mix freely with the other passengers upon the coastwise steamers.

In the Indian United Provinces within the last twenty years there has been a marked decline of the disease, and the *Times of India* remarks that "in India at any rate, probably in the wide world, no man acquainted with the literature or practice of leprosy, would for a moment hold that contagiousness, etymologically interpreted, can be set down as a predicable character." Dr. Hansen, in answer to an inquiry by the Leprosy Committee in London, "If the disease had ever spread among the population of Bergen, or the attendants in its leper asylums," replied that for many years there had not been an instance of a Bergen student becoming affected, nor during the whole period of their existence had there been any case among the nurses, or servants, or staff of the asylums, with the single exception of one washerwoman.

This agrees with the recorded experience of Captain Hunter in India, Dr. Max Sandreczki, for twenty-five years in the hospital at Jerusalem; Sir William Kynsey in Ceylon, and many others, including Dr. Danielssen of Bergen, Dr. Dixon, medical superintendent of Robben Island; the Superior Council of Health in Mexico, and Surgeon-General C. R. Francis in Calcutta. The minority, those who consider leprosy slightly contagious, is prominently represented by Dr. Hansen of Bergen, the Leprosy Commission of India, Dr. Philip R. Waughop, ex-Hawaiian Government Physician, and Dr. E. Baelz of Tokio, Japan, who believes it feebly contagious, but who has never observed a single case of transmission of the disease. Dr. Hansen informed the London Committee that he had spent ten months in a tour in the United States, chiefly in Minnesota and Dakota, and that he had been able to obtain no evidence of contagion in that country, and there appeared to be something in the conditions of life there which prevented the disease from spreading in that way.

A digest of the literature of leprosy will classify the disease as infectious, and mildly contagious, especially in its tubercular form, its virulence being largely modified or negatived by proper care, food, and good hygienic, sanitary, climatic, and physical conditions, as indicated by its general disappearance wherever these conditions are generally observed. It will indicate leprosy as permanently endemic only where these conditions are not maintained. That segregation in the endemic centers is extremely difficult and of little value in the prevention of the disease, but a source of comfort and a means of support to the impecunious sufferers. That while in certain extreme cases limited segregation is advisable and agreeable to the afflicted, to apply it indiscriminately is, as expressed in the report of the committee of the Medical Society of the County of New York, "arbitrary and unjustifiable."

Under the conditions outlined in the literature of the disease and of its treatment in the endemic centers, the conclusion that our treatment of its unfortunate subjects is based on ignorance or indifference regarding its true character seems perfectly justified.

Washington, D. C.

THE TARNIER FORCEPS.

To the Editor of the Medical Record:

Sir:—Your issue of April 3 contains a review of Dr. Joseph Brown Cooke's "Manual of Obstetrical Technique." Referring to Dr. Cooke's recommendation that the young practitioner be provided with the Tarnier forceps, your reviewer says that such advice is "of doubtful value, the experience of many being that it is a highly dangerous instrument in the hands of any but the most experienced." This is a remarkable statement. The special difficulties of the axis-traction instrument are very slight and are readily understood and overcome by any man who is fit to be entrusted with the care of a woman in labor. Instead of being more dangerous than the old-fashioned instrument, it is far safer, both for mother and child. Rotation takes place without the aid of art, traction is made in the right direction and with a minimum of force, there is less compression of the fetal head, and less traumatism of the maternal tissues. Instead of being more difficult, the operation is much easier, as those who have

given up the old method for the new can testify. If anyone should be taught the use of the axis-traction forceps it is the beginner, for if a man begins wrong he is not apt to change his methods later. My own convictions are the result of an extended and careful trial of the instrument, but if authorities are asked for there are so many that time and space would fail to cite them. In Paris, in Edinburgh, in Dublin at the Rotunda Hospital, in our own country at Johns Hopkins, and now in Berlin, where racial prejudice so long proved an obstacle, the Tarnier forceps has conquered its way and a knowledge of its use is considered an essential part of the equipment of the senior student and house surgeon. Not long ago a physician of this city, of large experience with the older instrument, had a case which he failed to deliver, and asked a colleague to come to his assistance prepared to perform craniotomy. The latter, upon his arrival, delivered with the Tarnier forceps and without especial difficulty a dead fetus. A case like this carries a warning so plain and so impressive that comment is idle. If Dr. Cooke can persuade our younger practitioners, and, for that matter, our older ones, to familiarize themselves with the modern method of forceps delivery, he will render a great service to them and to their patients.

George P. Shears, M.D.
203 West One Hundred and Third Street

Progress of Medical Science.

Boston Medical and Surgical Journal, April 15, 1909.

Treatment of Fibrinous and Serofibrinous Pleuritis.—F. S. Lord first considers pleurisy in its relations to tuberculosis. From animal experimentation with serous exudates in pleurisy and the after histories of cases of pleurisy, he comes to the conclusion that at least three-fourths of the primary cases with effusion are tuberculous. Out of every ten cases of primary fibrinous or serofibrinous pleurisy, at least three or four develop pulmonary or other tuberculosis within an average period of from four to six years. All of these cases should be treated as if they were tuberculosis until the contrary is proven. Outside of maintaining the general health at as high a level as possible, the usual measures of catharsis, diuresis, diaphoresis, and the thirst cure for pleuritic effusions are practically useless. A reduction in the amount of sodium chloride injected may be considered, but as yet it has not been demonstrated to be of great value for the removal of inflammatory fluids. In regard to tapping, we may so do in (1) large serofibrinous effusions, (2) those with pressure symptoms within a given time, and (3) double effusions. Small and medium effusions do not need immediate removal. For removal of the fluid commendation is given to the airtight trochar in connection with the familiar bottle aspirator. In primary and uncomplicated pleurisy with effusion, in young subjects with symptoms of one, two or three weeks' duration, the evacuation of fluid which flows in response to slight negative pressure may apparently be safely continued until the first moment of cough, pain or dyspnœa-pressure or other discomfort. In cases of longer duration, however, or in those with complicating cardiac, pulmonary or mediastinal disease, and in patients past middle life, the first operation may well be regarded as an experiment, in which, to be sure, unfortunate accidents are extremely uncommon, and not wholly avoidable. They are less likely to occur if only a small amount of fluid is slowly withdrawn without forcible aspiration.

Therapeutic Value of Rattlesnake Venom in Pulmonary Consumption, Acute and Chronic Bronchitis, Etc., and in Some Well-Recognized Neuroses.—This preliminary paper of T. J. Mays summarizes the histories of thirty-two cases. The name of the remedy is crotalin, and is the dried yellow residue of evaporated venom and is soluble in water and glycerin. Hypodermic dose ranges from 1-100 to 1-200 grain, once or twice a week. The author claims that the improvement in his patients was certainly due to the crotalin, but a review of the histories given renders it advisable to accept this conclusion with the customary allowance.

New York Medical Journal, April 17, 1909.

The Surgical Treatment of Epilepsy.—W. B. Case says that there is no question as to the propriety of operating on certain cases of epilepsy, but his own results have been so encouraging that he feels that they justify further trial in cases of idiopathic or obscure origin even when of long standing. Every case of epilepsy should be carefully examined for source of peripheral irritation, and especially for faulty digestion or intestinal diseases. If no peripheral irritation can be found, he says these cases should be operated on for the following reasons: (1) Because they are otherwise absolutely hopeless, unable to enjoy life, and a nuisance, or even a menace to those who have to care for them, for they frequently develop attacks of homicidal mania; (2) because some, even of the worst cases, may be cured. And it is impossible to foretell which can, and which cannot, be cured. (3) Because those patients not cured are usually benefited temporarily to a sufficient extent to make them glad they had the operation. (4) Because there is so little danger in the operation. All his patients recovered from the operation, and all that he knows of personally have recovered. (5) The lack of pain and discomfort following operations upon the brain. He adds the following observations as to the technique of the operation and gives the tabulated results of his own cases. A large osteoplastic flap should be made over the region to which the focal symptoms point, or if there are none, the flap may be made so as to expose the Rolandic area on either side. This can be rapidly done with a good de Vilbiss craniotome, but not with one that has been bent or twisted out of shape. It gives plenty of room for examining nearly the whole hemisphere, and for tying such bleeding points as are bound to occur. A large crucial, or triangular incision should be made in the dura, and a careful examination made for pachymeningitis, depressed bone, new growths, or any other suspected lesion. Any offending body should be removed. No harm results from removal of a large amount of thickened dura when there is an osteoplastic flap to cover the wound, but this would be dangerous where much bone had been removed with the trephine or rongeurs, as cerebral hernia would be likely to follow. Edema should be drained by the careful introduction of grooved directors into the brain substance. In some cases serum flows in streams, and the translucent brain may be seen to shrink and become opaque in a few moments. Several directors may be introduced at once. Of course, no lateral movement tearing the brain should ever be made. Exploring needles are useless. A soft rubber drain may be put just through the dura and brought out through one of the small trephine holes. Sometimes gauze packing may be used in the same way to prevent oozing; but remember that gauze does not drain. The author thinks it possible that his good results were due to the large opening, and wide inspection of the brain, and that the absence of bad results, particularly cerebral hernia, may have been due to the replacing of the bone flap.

The Importance of Cerebral Lesions Complicating Suppurative Otitis.—S. MacCuen Smith enumerates the symptoms of diagnostic value and says that there still exists great difficulty in localizing the exact site of the head lesion. From the fact that a large majority of abscess formations involving the interior of the skull enter through carious erosion of the tegmen tympani or tegmen antri, we should always carefully examine these regions during the course of a mastoid operation. In about one-half of such cases the dura is noticeably diseased, and will be found firmly adherent to the brain, these adhesions frequently acting as a barrier against the further development of a localized meningitis. Not long since we looked for abscess of the brain complicating the chronic form of suppurative otitis media almost exclusively, but in recent years our observations have taught us that the acute type is also productive of many such cases, thus clearly demonstrating the value of prophylaxis as furnished by early operative intervention. The author gives a hearty endorsement of Whiting's encephaloscope. He considers it usually unadvisable to irrigate acute abscess cavities, but in chronic cases in which the pus is thick and foul-smelling, such a measure is useful. In regard to the question of the advisability of a counter opening one and one-quarter inches above the middle of the external auditory canal, he says that he has never found this necessary as in all his uncomplicated cases of temporosphenoidal abscess, those that have been given ample drainage through the middle ear have recovered. In the absence of sufficient evidence of disease either of the tegmen antri or tegmen tympani to warrant intervention in this locality, the usual operation through the squamous portion of the temporal bone should be performed.

Longevity and Rejuvenescence.—J. I. Nascher says that the decline due to old age is not a retrogression of development. Not a single organ or function reverts to an infantile or youthful type. Instead, there is a change in the character or composition of an organ which impairs its action or causes abnormal action gradually more pronounced. The change is not sudden but very gradual, and

the author traces the course of events in the various bodily systems. He notes the present-day tendency to shorten the period of development and increase the mental and physical capacities, pass over the period of maturity with indifference and endeavor to lengthen the period of decline. We ignore the mode of living of those who lead a natural existence terminating in a natural death. Instead of shortening the period of development we should endeavor to lengthen it. Mental and physical tasks should not be carried to the point of fatigue. We should give more attention to the amount of sleep required at the various periods of life. But as long as men of modern life do not feel harm, they will not believe in its existence. Rejuvenescence depends primarily upon increased mental activity, and this in turn stimulates physical activity and vigor. Definite recommendations by the author are a young wife, change of scene and residence, and a complete change in the mode of living. Phosphorus is the only drug which produces a lasting mental stimulation without a depressing reaction. Rejuvenescence in the aged is, however, only a temporary condition. Increased physical activity stimulates the anabolic processes and unless the catabolic processes can be stimulated as well, the individual hastens the inevitable end. The best form of exercise is walking up a moderate incline with frequent rests.

Long Life and Hot Climates.—W. F. Robinson, who lives in Florida, says that the average successful business man who forms the habit at the age of 50 or therabouts, of spending three months of each winter in the South, thus avoiding the Northern winter, will almost certainly prolong his life for ten years, and as well greatly increase the enjoyment of his later days. The most trying of all times in Northern climates is the early spring. It is trying to the system, which has become reduced by the rigors of winter and equally so to one which has become relaxed by a visit to the South. The month of April is especially trying so that Northern visitors to the South should not return before May 1. The author has lived in both sections of the country, and his paper records the result of the effects of the change in his own system.

Journal of the American Medical Association, April 17, 1909.

Sewage and Tidal Waters.—G. A. Soper describes the problems that have to be met by sanitary engineers in the disposal of sewage in rivers, harbors and tidal waters. The necessity of this has become apparent within the past sixty years, and now of the twenty-six cities of Europe and America which have populations of over 500,000, about one-half purify their sewage or follow some carefully devised plan for disposing of it. The self-purification of a harbor for assimilating sewage without offense, varies according to its shape and the tidal currents that flow to and from the ocean. When sewage is discharged on a rising tide it is not only apt to be carried toward the land but also to be deposited on the shores, and this is particularly true in long and narrow harbors. There should be, therefore, a net seaward discharge and the utilization of outgoing currents and whatever aids the seeward carriage and aids diffusion would seem advisable. Diffusion is at the very heart of the question of utilizing the digestive power of a harbor for sewage. There is no insuperable difficulty in the purification of sewage, except the cost. This for a very large city would be enormous, but, fortunately, it is not always necessary to purify all the sewage produced in cities bordering on tidal harbors—it may sometimes be enough to purify the discharge of some of the principal sewers, and even then the highest degree of purification may not be needed in every case, but only enough to make the sewage harmless when finally discharged into the tidal waters. Contrary to general belief, it seems impossible to recover the manurial ingredients of the sewage in such a way as to reduce the cost of handling it, and the bacterial processes that have been perfected do not aim to recover the fertilizing matters. It is true that sewage irrigation has been utilized in some large cities, notably Paris and Berlin, but this requires great areas of land and is profitable when the suitable land is cheap or the sewage is useful for the water it contains. Screening, settling and grease removing are extensively practised in Germany when sewage is emptied into rivers which are not used for drinking purposes; the cost is comparatively small and the esthetic advantage is large. Sewage purifies itself through aëration by a process of slow combustion. Where this does not happen offensive smells are produced, but these do not themselves convey infection, and there is not much evidence that a large amount of sickness is produced by simple harbor pollution.

Delirium Tremens.—T. W. Ranson summarizes his conclusions from his study of 500 cases of delirium tremens in Cook County Hospital as follows: "(1) In incipient cases the patients respond readily to treatment with chloral, ergot, bromids and whiskey, the drugs being mentioned in the order of their value; (2) delirious patients are very resistant to treatment. In the cases studied, the administration of the sedative drugs increased the mortality. This was most evident when scopolamin was used, that drug increasing the mortality 13 per cent. These unsatisfactory results with the sedative drugs were due to the large doses used. It will be shown that small quantities, for example, from 15 to 30 grains of chloral in twenty-four hours, may be given with good results, but that when larger quantities are given the death rate increases with the amount of sedative administered. (3) The only drug which reduced the mortality was ergot. By its use the death rate was decreased 21.6 per cent. (4) When whiskey was given the mortality was increased 1.8 per cent." These cases constituted the admissions to the hospital for this condition between June, 1905, and August, 1908. They were classified, according to their peculiarities and the treatment employed, by means of a system of library cards. It is noted in addition to the statements embodied in the conclusions that when whiskey was used it seemed to have some decided value in incipient cases, lowering the percentage of patients becoming delirious by 20.2 per cent. But in the cases with delirium the mortality was raised 1.8 per cent. Stomachics were used extensively, but were not taken account of in these statistics, and generally drugs are not of such value that other therapeutic measures can be neglected, and this is especially true for the wildly delirious patients, for whom much more can be done by nursing than by drugs. Ranson emphasizes the importance of proper methods of restraint, frequent giving of liquids, and the use of sedative baths. In the incipient cases, drugs are useful, but in cases of delirium care must be taken not to overdose the patient. In case of failing heart action or passage from delirium to stupor and coma, heart stimulants should be given hypodermically.

The Blood After Splenectomy.—J. Myers reports the results of systematic blood examinations in a case of splenectomy in a boy eleven years of age, who suffered a stellate rupture of the organ from a fall from a tree. The operation by Dr. Vander Veer was a success and the recovery seemed complete, the boy a year later being apparently normal in all respects. The blood findings are tabulated and show a very remarkable variability in the red blood cell count, and the hemoglobin content normal or above normal, with no signs of even a moderate anemia. The leucocyte count was persistently above normal with a marked predominance of the lymphocytes. There is, however, a marked lack of neutrophile polynuclear cells which only dominated during an intracurrent gastric disturbance, showing that the ordinary relations between inflammation and polynuclear hyperleucocytosis are still striving to exist. Myers says: "That the removal of the spleen, which in embryologic life manufactures lymphocytes, gives a stimulus to the lymphatic apparatus of the body and thus causes a hyperlymphocytosis, is probable; that this stimulus is very great is evidenced by the lack of neutrophilic polynuclear hyperleucocytosis where we should naturally expect it; that it is lasting is evidenced by the relative and absolute hyperlymphocytosis seen late, after splenectomy."

Paralytic Ileus.—C. H. McKenna reports two cases of paralytic ileus in which the patients were operated on successfully by laparotomy and opening a loop of the intestine and irrigation. The conditions calling for these measures are the extreme ones in which all other methods have failed and when death is apparently imminent, as in paralytic ileus following operation or accompanying typhoid fever; injuries to and diseased conditions of the spinal column producing intestinal paralysis; and extreme abdominal distension accompanying suppurative peritonitis. He found in these cases that very little gas escapes when the bowel is incised. Consequently stress is laid on the introduction of long tubes into the intestines, since the irrigation solution, by entering the bowel at considerable distance from the opening, mechanically forces the gas and fecal matter to escape, besides acting as a stimulant to peristalsis.

Stream Pollution.—M. L. Price and W. R. Stokes remark that the pollution of streams by distillery waste is a comparatively recent problem since the concentration of the distilleries, due to changes in the trade, in the neighborhood of cities and in thickly settled communities has given rise to nuisances varying in extent according to the process employed and the size of the stream receiving the waste. The legal principles involved are fairly settled, but their application to this particular question is

somewhat new. In the specific case referred to in this paper, the pollution of the Patapsco River, it was necessary to show the pollution and its cause, and the latter is of interest on account of the fungus to which it was found to be due. The species which caused an almost intolerable odor from the water of the river a short distance below the distillery and killed a large number of the fish, was found to be *Leptomitus lacteus*, an alga belonging to the *Saprolegniæ*, which is described and illustrated. When cultivated *in vitro* it quickly disappeared, which the authors attribute to its exhaustion of its own nutriment as well as to autointoxication by its own products. The cause of the death of the fishes was not ascertained by the examinations made. The article is illustrated.

The Loncet, April 10, 1909.

The Etiology of Acne Vulgaris and Its Treatment by Vaccines.—A. Fleming refers to the various microorganisms found in the pustules of acne and dwells especially on the bottle bacillus, so called from its shape. It presents an appearance very much like yeast. It occurs in the more superficial part of the comedo, and is found constantly in dry seborrhoeic conditions of the scalp. The bacillus is a pus-producing organism as it is constantly present in the pus, is frequently the only organism there, can be recovered from the pus in pure culture and if inoculated into the skin of susceptible individuals produces a pustular folliculitis while examination of the pus shows no other organism present. Inoculated into animals, it produces a local abscess from which the bacillus is recovered in pure culture. The serum of patients affected with acne agglutinates the bacillus in some cases. The opsonic index of patients to the acne bacillus varies considerably from normal. Large doses of a vaccine derived from the acne bacillus have induced a marked negative phase characterized by the appearance of fresh pustules from which the bacillus has been recovered in pure culture. A vaccine from this organism has a marked beneficial effect on the condition. When a patient has a marked high opsonic index to the bacillus, his condition improves, but when the opsonic index is low, fresh pustules appear. The paper closes with details of several clinical cases.

Physiological and Therapeutical Properties of the Serum of Milk (Lacto-Serum).—R. Blondel says that lacto-serum, which is obtained by a special process of filtration, behaves as regards its saline constituents like a fluid in which are dissolved common salt, milk sugar, and phosphates of the alkalies and alkaline earths. As regards its ferments it has a resemblance to extracts of animal organs and to animal serums. It contains also several oxydases. Injected into animals the serum causes a slight rise of temperature, increase in the polynuclear leucocytes and an excretion of uric acid. There is a special effect, viz., a notable lowering of the blood-pressure in the capillaries and arteries. The author has given lacto-serum in puerperal infections with sometimes benefit and sometimes not, in post-operative peritonitis without effect, in typhoid fever with indefinite results, in pneumonia with distinctly successful results, and in the hypertension of arteriosclerosis. In this last condition the effects have been constant and beneficial. All the usual symptoms have been quieted or removed. The daily dose by injection has been 10 c.c. and it has been repeated in 24 hours until the blood-pressure becomes normal. Then the injections are given at greater intervals for a month. They are made into the thigh muscles or gluteal regions, or under the skin of the flanks. Usually there is no pain, and in the author's hands no abscesses have occurred in over a thousand injections. Full directions for the preparation of the lacto-serum are given.

Treatment of Graves's Disease with the Milk of Thyroidless Goats.—W. Edmunds summarizes results obtained in 15 cases. In general, these were satisfactory and encouraging. The author notes that as the anti-body in the milk must be derived from the blood serum, it would seem to be better to administer the dried serum and corpuscles from a thyroidless animal. But there is one point in favor of the milk. Ordinary cow's milk must contain a certain amount of thyroid secretion, therefore, we have either to give this or cut ourselves off from a valuable article of diet for invalids. The use of milk from thyroidless animals relieves us from this dilemma. The amount of thyroid secretion can also be reduced by removal of part of the patient's thyroid. Mortality in this operation has been great in the past, but is less under the conditions of modern surgery. Operation should not be delayed until the patient has become weakened by disease. Even assuming the success of surgery, we still need in this malady a medical therapy for those cases too mild to call for operation, for those too ill for it, or for those who decline to have it done; also for those cases operated on with but partial success. Of the author's 15 cases, 13 distinctly improved.

British Medical Journal, April 10, 1909.

The Nerve Sheath in the Causation and Treatment of Neuralgia.—R. M. Simon says that the connective tissue which forms a nerve sheath is continuous externally with the connective tissue outside it, and from its inner surface fine trabeculæ of connective tissue extend to form a protective covering between and around the myelin and axis cylinders of the nerve elements. Blood-vessels are carried in all these structures of connective tissue, and the author believes that it is upon the congestion of all these vessels that the pain depends. There is no lymph space between the sheath and the nerve elements proper, and for this very reason any material overfulness of the vessels of the sheath or a very slight edema around them or exudation into the lymph spaces in the interstices of the sheath will of necessity cause an amount of pain out of all proportion to the pain which would be caused by an equal or vastly greater effusion outside and around the sheath itself. Acting on the theory thus advanced, the author advises stretching of the nerve inside the sheath, cutting down upon the trunk in order to do this. In some instances acupuncture, which undoubtedly relieves some cases, probably so does by setting free the fluid accumulated between the nerve sheath and myelin of the nerve. The nerve sheath should be opened and all internal adhesions separated. Two illustrative cases are given.

Aural Vertigo.—A general description of this condition is given by W. S. Syme, who says that the name proposed by Ménière years ago has been extended to cover various clinical states which are very diverse. The three cardinal symptoms of Ménière's disease are sudden deafness, loud subjective noises, and severe vertigo, and this complex should alone be called after the discoverer of the malady in question, except for the fact it is bad policy to name diseases except on a pathological basis. The author, therefore, uses the name aural vertigo. He goes in full into the anatomy and physiology of the internal ear and then takes up the questions of pathology and diagnosis. Then follow paragraphs on course and treatment. In vertigo occurring in nonsuppurative disease of the middle ear, in which the vertigo has shown itself much later than the tinnitus and the deafness, it has seemed to the author that the treatment of the aural condition was more likely to lead to the improvement or disappearance of the vertigo. The best drug is quinine. On the ground that vertigo is due to anemia of the labyrinth, amyl nitrite has been suggested. The bromides and iodides are often useful, and pilocarpine, especially in patients in whom the aural condition is dependent on congenital or tertiary syphilis. Repeated lumbar puncture has helped some patients. All excitement should be avoided, and the bowels kept open. During an acute attack the patient should lie down and apply ice to the head. When all measures fail and life is intolerable, the static portion of the labyrinth may be destroyed by operation, or it may be possible, as Balance has suggested, to divide the vestibular nerve (as distinct from the auditory) before it enters the internal auditory meatus.

Lead Poisoning in Childhood.—A. J. Turner, who practices in Queensland, notes the fact that lead poisoning is endemic in his territory, and follows Gibson in attributing it to the lead paint of the buildings in that locality. Exposed to the hot sun of summer, the paint rapidly withers and becomes reduced to a powdery condition. This is particularly noticeable on veranda railings. These verandas are favorite playing places for the children whose moist hands become covered with the poison as they clasp the railings. Thence it gets to the mouth, especially in children who suck their fingers or bite their nails. This explains why the malady is common in town children but not in the country where the buildings are rarely painted, why it is more common in summer, and why it frequently picks out only one child in a family, the victim being the finger-sucker or nail-biter. The author does not deny, of course, the occurrence of cases from other sources. He recommends that other substances than lead should be used in painting places children use as playgrounds. The bad habits in the children as referred to must be corrected. It is useless to remove a child to the hospital and then after it is cured send it back to bad surroundings. Lead paint is dangerous only when it is fresh and sticky or dry and powdery. In regard to breaking up the habit of biting the nails, the author says that the best way is to put straight splints over the elbows. This may seem harsh treatment, but milder measures generally fail

Etiology of Oxaluria.—R. W. Burkitt of Eastern Bengal notes the occurrence of oxaluria among the Manipuris, who differ from the other races of the same general district in that they eat only vegetables and fruit. They suffer from gravel, always of the calcium oxalate variety, and their urines when fresh contain no other crystal. They present the usual symptoms of renal gravel and soon recover on urotropin and potassium citrate. Examination of the soil and drinking water of the locality shows a great deficiency of lime salts. It is necessary in order to keep in health for both men and animals to take calcium chloride in their diet. Other races living in the same locality who eat flesh as well as vegetables do not suffer, providing that they add lime to their food.

Unna's Method of Treating Leg Ulcers.—H. Barr adds charcoal to the familiar paste, using 18 parts to 6 of zinc oxide, 6 of boric acid, 16 of gelatine, 20 of glycerine and 50 of water. The gelatine and a portion of the glycerine are soaked in water for 12 hours. The remainder is mixed in to make a paste. Then all is heated on a water bath with stirring. The final product is poured into a shallow vessel. The ulcer is cleaned with boric acid fomentations and red lotion used if it is sluggish. At first the paste is left on for a week; later when healing well it can be left on for a fortnight. The waxy nature of the bandage used prevents it adhering and tearing off the epithelium. A carbolic (resin) bandage is wound tightly round the leg covering the ulcer and going a little above and below. The paste is painted well over the site of the ulcer and if much discharge is feared it may be dabbed with cotton-wool. An ordinary bandage is then wound round all, while a small piece of carbolic bandage cut to size lies on the bed of the ulcer.

Berliner klinische Wochenschrift, March 29, 1909.

Cancer Statistics.—Orth publishes the cancer statistics of the Charité Hospital in Berlin, comparing his figures with those of Virchow. The number of deaths from cancer in this hospital shows a gradual increase from 4.9 per cent. in the year 1875 to 12.2 per cent. in 1908. As the pathological diagnosis of cancer has not been very much changed in these years, the increase in incidence of the disease must be admitted. Cancers of stomach and of uterus are still the most frequent forms of the disease so far as site is concerned. That clinical diagnoses are inaccurate in this respect is shown by the fact that cancer of the liver is given in English reports as comprising 14 per cent. of deaths from this disease; Orth's figures on the other hand show but two cases of primary liver cancer during five years. Women are more frequently the subjects of cancer because of the frequency with which the uterus is attacked by the disease. The fact that cancer of the male genital organs is very rare speaks strongly against the contagiousness of the malignant disease. In addition to increase of cancer mortality Orth's figures show likewise that the cancer age must now be placed at much lower figures than formerly, the disease being now much more frequent in comparatively young individuals than can be concluded from older figures.

Münchener medizinische Wochenschrift, March 30, 1909.

Coxa Vara After Reduction of Congenital Dislocation of the Hip.—Joachimstal says that recent literature contains many instances of complications which arose after bloodless reductions of congenital hip dislocations. One very important complication is the appearance of coxa vara. This has occurred four times in 150 cases treated by the author, the *x*-ray pictures taken before the reduction showing quite normal inclination of the neck of the femur, which must have gradually approached a right angle. All cases occurred in young infants who after recovering good function at the hip joint after a reduction of the dislocation showed recurrence of the limp, though the dislocation did not recur. The explanation of this complication is difficult because of the perfectly normal position of the neck before the operation. It may be due to a congenital weakness of the femur at this site, which shows itself as soon as the reduction of the dislocation allows the weight of the body to fall upon this part of the bone. It is also possible that the trauma of the operation may act as a predisposing cause to the occurrence of a coxa vara, especially as the long fixation of the hip in a splint weakens the bone still further. The fact that such complication may occur should lead to as short a duration of immobilizing the limb as possible. Moreover, *x*-ray examinations should be made from time to time, so that the tendency to the development of the deformity may be discovered as early as possible, and proper measures taken to prevent it.

Anesthesia of the Eardrum.—Tiefenthal uses the following procedure to procure anesthesia in paracentesis of the tympanic membrane. He introduces four drops of 20 per cent. solution of cocaine, to which one drop of 1:1000 solution of adrenalin hydrochloride has been added into the external meatus and allows this mixture to remain in contact with the eardrum for fifteen minutes. This leads to partial anesthesia of the drum. Then two to four drops of a mixture prepared by adding two drops of 1:1000 adrenalin solution to 5 or 10 per cent. solution of cocaine hydrochloride are introduced into the middle ear by means of a syringe the needle of which is made to pierce the partly anesthetized drum. Usually the needle is introduced through the lowermost part of the membrane so as to avoid any injury to the structures of the middle ear. In a few seconds there results an intense anemia of the eardrum accompanied by perfect anesthesia. Paracentesis of the membrane may then be performed without pain and without bleeding.

Deutsche medizinische Wochenschrift, April 1, 1909.

Prostatectomy.—Cahn reports forty cases of suprapubic prostatectomy performed by Israel. The age of the patients was from fifty to eighty years and their chief complaint consisted in the disturbance of urination, which led to prolonged use of the catheter. Most of the patients were infected so far as the bladder was concerned, and all retained a considerable amount of residual urine. Thirty per cent. of them had vesical calculi in addition. The following conditions were looked upon as indicating an operation: the failure of the catheter to remove all residual urine, repeated attacks of pyelitis, the occurrence of hematuria or much pain during catheterization, and spontaneous hematuria. Bad general condition and very much impaired nutrition were looked upon as contra-indications to operative interference; diabetes must be considered a serious complication acting as a relative contra-indication one of Israel's diabetic patients dying of coma after the operation. Infection of the bladder was not considered as a contraindication, though in several instances the operation had to be performed in two stages, the bladder being first drained and the infection diminished in extent or completely cured. Old age was not considered as forbidding an operation, for a number of aged patients were greatly relieved by the surgical treatment. Before the operation the cystitis was treated by regular catheterization, by bladder irrigations, and in certain cases by a preliminary drainage of the bladder through an artificial fistula. Suprapubic enucleation was the only operation performed, lobar anesthesia being used in recent years. Post-operative complications consisted in hemorrhages and in inflammation of the testicles or of the epidydimis. In no case was there a fatal outcome caused by these conditions. Of the forty patients six died after the operation, one of uremia, one of diabetic coma, two of pulmonary embolism, one of pneumonia, and one of general peritonitis. Ninety-four per cent. of the surviving patients were discharged cured, two patients only continuing to suffer from incontinence or from cystitis. The pathological findings lead Cahn to conclude that the hypertrophy is due to a true neoplasm originating in the glandular epithelium of the organ. The picture was that of a papillary adenomata, which quite explained the possibility of recurrence of the tumor or the frequent transformation into a malignant epithelial new growth. Inflammatory conditions have nothing to do with the origin of a prostatic hypertrophy.

Tracheobronchial Adenopathies in Their Relation to Chronic Pulmonary Tuberculosis in Children.—Charles Leroux shows that the frequency of enlargement of the bronchial glands is great in nursing infants and young children, while in children from twelve to fifteen years of age tuberculosis of the pulmonary apex is more frequent. The author says that in nearly all cases of enlargement of the bronchial glands a diagnosis is possible if looked for in the right way. Radioscopy is of great value in recognizing these glandular enlargements. The physical signs are rough respiration at the apex of the lung without increased vibration or bronchophony. As soon as bronchophony or increased vibration can be recognized there is probably involvement of the apex. The source of the tuberculosis is rarely from the intestine. It arrives much more frequently by the lymphatics from the nasopharynx or the skin reaching the cervical or subclavicular glands. Or it may come from a pleurisy or pneumonia that has left a good soil for the development of the germs. This is one of the most curable forms of tuberculosis although if uncured it may end in pulmonary meningeal or peripheral tuberculosis. It is necessary to remove these children from their unhygienic surroundings and place them in the country or at the seaside for a considerable period, since a short sojourn does not give a permanent cure.—*Annales de Médecine et de Chirurgie Infantiles.*

Book Reviews.

Atlas of Clinical Surgery. With Special Reference to Diagnosis and Treatment for Practitioners and Students. By Dr. Philip Bockenheimer, Professor of Surgery in the University of Berlin. English Adaptation by C. F. Marshall, M.D., F.R.C.S., Late Assistant Surgeon to the Hospital for Diseases of the Skin, London. With 150 Colored Figures from Models, by F. Kolbow, in the Pathoplastic Institute of Berlin. Three Volumes. New York: Rebman Co., 1908.

The three volumes included under the above title are noteworthy for the magnificent collection of plates which they contain. These plates are photographic reproductions in color of models made by Kolbow, the well-known plastic modeler of Berlin, and are taken from cases seen at the von Bergmann clinic. Not all surgical diseases can, however, be pictured in this way, and the "Atlas" therefore has its limitations, as may be readily seen from a glance at the table of contents. The first volume is largely devoted to neoplasms and examples of nearly all are presented, which are evident by inspection. Interspersed are representations of phymosis, balanitis, fistulæ, etc. The second volume is taken up with the infections and their complications. The third is a continuation of the same topic, with a number of minor subjects. No attempt is made to classify this material.

The text which accompanies these plates is not particularly noteworthy, the only feature being the differential diagnosis, which is graphically illustrated by the pictures. It comprises largely the teachings of the von Bergmann school, and all the cases were under the author's observation. The translation is very clear and concise. If one inquires more closely into the actual value of a publication of this kind, of which many have appeared in recent years, the answer may be somewhat difficult to state. Their relatively high cost places them beyond the reach of the average medical student, for whom it is stated that they are intended, and the practitioner is in need of more extensive information of the topics presented.

Arteriosclerosis. Etiology, Pathology, Diagnosis, Prognosis, Prophylaxis, and Treatment. By Louis M. Warfield, A.B., M.D., Instructor in Medicine, Washington University Medical Department; Physician to the Protestant Hospital; Adjunct Attending Physician to the Martha Parsons Hospital for Children, St. Louis, Mo.; Formerly Medical House Officer at the Johns Hopkins Hospital, Baltimore, Md.; Member St. Louis Medical Society, Missouri State Medical Society, and American Medical Association, etc. With an Introduction by W. S. Thayer, M.D., Professor of Clinical Medicine, Johns Hopkins University. Eight Original Illustrations. St. Louis, Mo.: C. V. Mosby, 1908.

The subject of arteriosclerosis, although often discussed in text books and journals, is as yet sufficiently misunderstood to warrant the appearance of such a monograph as the one before us. The writer treats of it as a disease rather than as a complication or symptom group, and gives much evidence in favor of his viewpoint. His subject has been divided in the classical way—anatomy, physiology, pathology, etiology, symptoms, diagnosis, prognosis, prevention, and treatment. A great deal of stress is laid upon hygiene, diet, rest, exercise, good habits, etc. Balneotherapy is recommended, although the author sees too much danger in a hot bath due to the increased heart's action, forgetting that its effect is much like that of amyl nitrite in causing acceleration of the pulse, but with the saving grace of a fall in arterial pressure. Throughout the work the writer shows a broad knowledge of his subject, decries drugging, and recommends that the patient be treated rather than the disease.

Leitfaden der Hygiene, für Studierende, Ärzte, Architecten, Ingenieure, und Verwaltungsbeamte. Von Dr Aug. Gärtner, o.o. Professor der Hygiene und Direktor des hygienischen Institutes der Universität Jena. Mit 190 Abbildungen. Fünfte, vermehrte und verbesserte Auflage. Berlin: Verlag von S. Karger, 1909.

Dr. Gärtner's book on hygiene is one of the most popular text books in Germany. The present edition is much larger in size in comparison with preceding issues, the recent developments in the art and science of the subject, and especially in the field of prevention of infectious diseases, having called for a thorough revision of the book and many additions to the text. The subjects considered consist in the study of the relations of atmosphere, water, and the earth's surface to public health and to the health of the individual; the foodstuffs used by mankind; the construction, the ventilation, and the heating of houses; clothing; sewerage systems; school hygiene, industrial hygiene, and the causation and prevention of infectious diseases. The curricula of American medical colleges give but little time to the all important subject of hygiene, and careful reading of a book such as Dr. Gartner's will go far in filling the gaps in the average physician's knowledge of the subject.

Friedberger and Fröhner's Veterinary Pathology. Authorized Translation, Translated by M. H. Hayes, F.R.C.V.S. With Notes on Bacteriology by Prof. R. Tanner Hewlett, M.D., F.R.C.P., M.R.C.S., D.P.H. In two volumes. Sixth edition, revised and enlarged. London: Hurst & Blackett, Ltd. Chicago: W. T. Keener & Co., 1908.

This is the authorized translation of the sixth edition of Friedberger and Fröhner's standard work on Veterinary Pathology. In this edition the division of the volumes and chapters conforms to that of the original German text. The first volume contains chapters on: Diseases of the organs of digestion; diseases of the esophagus; diseases of the stomach; diseases of the liver; diseases of the peritoneum; diseases of the spleen; diseases of the urinary organs; diseases of the sexual organs; diseases of the heart and larger blood vessels; skin diseases; diseases of the locomotory organs; trichinosis in swine; "measles" of domestic animals; Miescher's tubes or Rainey's corpuscles; diseases of the nervous system; diseases of the spinal cord and of its membranes; diseases of the peripheral nerves; neuroses without known anatomical basis, and an appendix to diseases of the nervous system. In the second volume are chapters dealing with: Diseases of the respiratory system; diseases of the accessory cavities of the nose; diseases of the larynx; diseases of the trachea and bronchi; diseases of the lungs; diseases of the pleura; chronic constitutional disease, and infective or infectious diseases. At the end of the volume are Hewlett's notes on bacteriology, which are admirable; and an index to the two volumes. In case another edition is issued it would be well to insert a table of contents in the second volume.

Saunders's Pocket Medical Formulary. With an Appendix. Containing Posological Table; Formulæ and Doses for Hypodermic Medication; Poisons and Their Antidotes; Diameters of the Female Pelvis and Fetal Head; Obstetrical Table; Diet List for Various Diseases; Materials and Drugs Used in Antiseptic Surgery; Treatment of Asphyxia from Drowning; Surgical Remembrancer; Tables of Incompatibles; Eruptive Fevers; Weights and Measures, etc. By William M. Powell, M.D., Author of "Essentials of Diseases of Children," Member of the Philadelphia Pathological Society, etc. Ninth edition, thoroughly revised, enlarged, and adapted to the eighth revision (1905) of the U. S. Pharmacopeia. Philadelphia and London: W. B. Saunders, 1909.

There are probably about a couple of thousand prescriptions in this volume, enough, and more than enough, to satisfy or bewilder the most ardent seeker after this kind of knowledge. Several blank pages are interspersed throughout the book, so that even more prescriptions can be added; and the volume concludes with about sixty pages of miscellaneous information, useful to the physician. Many of the prescriptions have well-known names appended to them, but some (*e. g.* the first one under orchitis) are hardly to be dispensed by the average druggist.

The Arteries of the Gastrointestinal Tract. With Inosculation Circle. Anatomy and Physiology, with Application of Treatment. By Byron Robinson, B.S., M.D., Chicago, Ill.; Professor of Gynecology and Diseases of the Abdominal Viscera in Chicago College of Medicine and Surgery, etc. Chicago: E. H. Colgrove.

In this volume are described (1) the concentric gastric circles, (2) the ileocolic circle, (3) the enterocolic circle, (4) the gastroenterocolic circle, (5) the pancreatic circle, and (6) the ileocolic arches. The following views are advocated, viz., Blood cures disease; a cell lives in water; a cell functionates in a fluid medium; the apparatus for executing visceral hyperemia is the "inosculation circle"; the object of the "inosculation circle" is to engorge, to congest its peripheral viscus, and to transport blood volume from one viscus to another. It is needless to say that the book represents solid original work on the part of the author, for this is characteristic of all that he publishes. Much of this volume has already appeared in several medical journals, hence some repetitions occur, as each section was completed independently and separately.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 18, 1909.

DR. JOHN A. WYETH IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Orthopedic Surgery and was devoted to the question, "What Shall We Do with Our Cripples?"

Methods of the Widener Industrial Training School for Crippled Children.—Dr. DE FOREST WILLARD of Philadelphia said that, according to the estimate of Rosenfeld, one-sixth of the inhabitants of Germany were more or less crippled and that if this great number could be made self-sustaining it would mean an annual gain to the German Empire of $30,000,000 annually. If the Academy of Medicine could induce the Commissioner of Census to secure statistics as to the number of cripples in this country in 1910 it would be of great advantage. Such statistics would not contain the actual number, as many did not wish to class themselves as cripples. Weakened physically and handicapped as this class of unfortunates was, they were prone to become discouraged and even degenerate, though they might be well equipped mentally. Simply to place these crippled children in institutions offered no stimulation to their pride and no promise for the future. As many had active brains, in spite of their physical defects, they could be trained to earn a fair living. Many cases formerly regarded as hopeless were now capable of being improved by surgical methods, mechanical appliances, or common sense hygienic treatment. Since Stromeyer invoked tenotomy some eighty years ago to assist in the rectification of these deformities, there had been a steady advance until at the present time with tenotomies, myotomies, forcible corrections, osteotomies, transplantations of tendons and nerves, excisions, arthrodoses, etc., results could be achieved in a few weeks that formerly would have been regarded as miracles. Dr. Willard said that forty years ago he had determined to secure, if possible, first, a hospital where cripples could be either cured or greatly benefited by surgical, mechanical, and hygienic measures; secondly, to secure a fund for supplying these patients with the apparatus which was essential to their locomotion; thirdly, to educate and train each cripple along lines best suited to his physical deformities, mental condition, and powers of support; fourthly, to endeavor to educate medical students in the diagnosis and treatment of these cases and to open the eyes of surgeons to the fact that, while these patients were helpless, they were by no means hopeless; that it was a sin to pass carelessly over them simply because time, care, and patience were required for their relief. The hospital and funds had been secured, and he had endeavored to do his part in teaching what could be done in the way of curing and assisting these cases. About ten years ago he had presented the needs of this class of unfortunates to Mr. P. A. B. Widener, a philanthropist of Philadelphia, and as a result the Widener Memorial School was founded for the mental and manual training of crippled children. This school had been in operation but three years, and only children under ten years of age were admitted, so that, as yet, all the inmates were too young to have put into effect the methods which they hoped to develop within the next ten years. Mr. Widener had purchased thirty acres of land in the outskirts of the city, which presented a most attractive and elegant appearance as regarded grounds and buildings. Mr. Widener had expended $1,000,000 and had endowed the institution with $3,000,000. Here they endeavored to supplement the work of the hospitals, to strengthen and renew the weak ones and to educate them in habits of industry, order, cleanliness, self-respect and self-reliance and to apply such mental, moral, and religious training as would render them true, honorable, and useful citizens. Parents were expected to sign an indenture binding the child over to the trustees until it should reach its majority; in this way they were able to keep the children long enough to secure good results. Feeble-minded children were not eligible. In order to be admitted the child had to be a cripple, but improvable. There was a central hospital building, with every modern facility for the treatment of this class of cases. There were cottages for boys and girls, holding twenty. Each cottage was presided over by a house mother, who was expected to provide all the surroundings of a well-regulated home. There was also an educational, an industrial, an administrative, and an isolation building. Children were detained in the isolation building for three weeks after their admission to avoid the possibility of their conveying infectious disease. Then they were transferred to the hospital building, where they received such treatment as the case demanded. Much time was spent in the open air. There was an outdoor gymnasium and a broad playground. Glass-covered pavilions furnished winter playgrounds, which were always dry and free from snow. The children were constantly under the supervision of the resident physician and a trained nurse. As soon as the physical condition of the patient permitted, he was advanced to a cottage under the direct care of the house mother. At the proper age the children were sent to school, where the grades corresponded to those in the public schools. A few who showed unusual aptitude would be given a higher education. Those who showed unusual ability in vocal or instrumental music would receive a musical training that would enable them to earn a livelihood thereby. At a certain time manual training was begun, and the time devoted to it was gradually increased each year until an occupation or trade should be selected and mastered. The choice of a trade would be determined by the desire and inclination of the pupil and by his physical and mental ability. They endeavored to select such occupations as would employ the pupil's greatest earning capacity and were compatible with his taste and ability. As the oldest pupils were but fourteen years of age, the advanced grades of the manual training had not yet been established, but trades might be selected from the following: Farming, floriculture, care of poultry and stock, dairying, carpentry, woodwork, leatherwork, making of shoes, braces, crutches, tailoring, dressmaking, millinery, printing, cooking, housekeeping, and laundering. At the present time there were 91 children in the institution, and there were accommodations for 120. Already so much progress had been observed in the physical, mental, and moral development of the children that the founder and those in charge felt encouraged to continue the work, believing that the ultimate results would amply repay them for the great effort and cost of the undertaking.

The Opportunities for the Employment of Cripples.—Mr. W. FRANK PARSONS, Superintendent of the Charity Organization Society, said that it had long been an accepted truth that the best way to help others was to help them to help themselves. There was no provision in the city of New York for the industrial training of crippled adults, and what training there was for children had been but recently provided and was woefully inadequate. There had been but little effort to supply suitable employment and thus to save to self-support and self-respect those who were unfitted to engage on equal terms in the struggle for existence. The result had been a great waste of character and of charitable funds. Public begging had been for ages condoned as a recognized means of livelihood for cripples; many others were dependent upon relatives who could be partially or wholly self-supporting. It

was not easy to find employment for a cripple who was not trained relative to his disability. During one period of fifteen months there were 1,863 arrests of confirmed mendicants under the direction of the Charity Organization Society. Of these, 701 were physically defective and 447, or 24 per cent., of the entire number were crippled. This was vastly higher than the percentage of cripples in the general population. These figures illustrated the result of lack of industrial opportunity which must be encountered by each crippled person who was equipped with nothing but limited physical strength and limited bodily capacity. The mendicant cripples constituted but a small proportion of the cripples who were not self-supporting, and a smaller proportion of the entire number of cripples in the community.

The first organized effort to give the necessary attention to the opportunities for employment for cripples was the establishment of the Special Employment Bureau for the Handicapped, by the Charity Organization Society. This bureau registered cripples and persons handicapped in other ways and attempted to find employment for them suited to their mental and physical condition. Nearly all who received the services of this bureau were dependent upon others for support. During the fiscal year ending September 30, 1908, applications from 264 cripples were received. Of this number, 57 had been disabled by accident or loss of health, due to the nature of their previous employment. Two hundred and seven had become incapacitated through causes not connected with their previous employment. The total number of applications registered during this year was 1,217, and of these 477 were placed in steady employment at wages averaging $6.98 a week. Temporary work was found for 234, making a total of 711 handicapped persons who were helped during a year of great industrial depression. In the group of cripples, in addition to those handicapped by major operations, were included those having disabled limbs due to paralysis, old fractures, blood poisoning, tuberculous joint lesions, necrosis, rheumatism, and the loss of fingers. Two hundred and twenty-three persons so disabled applied for work during the year, and 57 were placed in steady employment at wages ranging from $3 to $24 a week, and averaging $7. Services of the kind rendered by this bureau, while they might increase in scope and efficiency, would never solve the problem of employment for the crippled. The bureau only tended to lighten the load of relief work which the community must carry. Its work was preventive in that it was the means of placing persons who were impaired in health in employment favorable to the arrest or cure of their diseases. The work was also educational in that it brought to the attention of employers persons who were able to do faithful and valuable work, and it awakened a feeling of responsibility on the part of employers toward their weaker brothers. It showed the number of individuals in the community who were objects of charity, and it demonstrated that cripples, even though handicapped, were often capable of employment, and that great economic waste could be avoided. The experience gained in the bureau had made very evident the necessity for three lines of special effort and study in connection with this subject. First, a study of the dangerous trades and the consequences of such employment on the health and capacity of those so employed. This should result in effectual measures to prevent the manufacture of cripples at the present appalling rate. Secondly, a study of all kinds of employment, and especially of factory work, to discover the particular places available for the employment of persons suffering disability of every kind and degree. Thirdly, the need of adequate and suitable specialized education and industrial training for crippled children starting life under the heavy handicap of ill-health and physical disability. The Special Employment Bureau had undertaken the second line of investigation. Such efforts as this were only remedial; the radical treatment of the problem lay in the universal opportunity for suitable education for crippled children. The best available census showed that there were 2,700 cripples of school age, and this estimate was incomplete. Some estimates placed the number as high as 7,000. In all schools and classes for such children there were registered 932 pupils. This indicated that there were at least 1,500 children in New York who were unable, because of physical disability, to attend the public schools and who were without educational advantages. The solution of the problem would require the devoted attention and cooperation of teachers, physicians and surgeons. There would be no lack of public support for the training of cripples that showed satisfactory results. The greatest danger was the inability to make efficient use of the means so rapidly becoming available. The difficulty would be in finding suitable teachers, those who could be both teacher and nurse, and who had that passion for public service which would lead them to know the children not only in school, but in their homes. Special school room equipment must be provided and a new curriculum devised for the crippled child.

The Care of the Injured and Crippled in Germany.—Dr. CHARLES H. JAEGER said that during the past twenty years 1,500,000,000 marks ($375,000,000) had been paid to sick, injured, and disabled workmen in Germany. This had been done under the compulsory insurance laws. Such laws had been adopted by nearly all European countries. The insurance covered sickness, accident, invalidity, and old age. The employee paid two-thirds of the premium and the employer one-third. All persons regularly employed in factories, mines, or railways, etc., had to be insured, while those intermittently employed were exempt. For example, if a workman received $6 per week, he paid $0.12 per week in assessments, and in case of sickness received $3 per week, besides medical attendance and medicines. The funeral indemnity in case of death was at least $20. Accident insurance was first instituted in 1884 and was confined chiefly to industrial enterprises, but had been since extended. This insurance was at the cost of the employers wholly. In general, all employees and overseers with salaries less than $750 per annum had to be insured. Compensation had to be paid, even though the negligence was on the part of the employee. Old age and invalidity insurance was enacted in 1889, and was made compulsory in the case of workmen over the age of sixteen years. This insurance fund was formed by equal contributions from the employer and employee. The German sick benefit association had sought to improve the hygienic conditions of employment and had provided lectures, relief stations, clinics, etc. An effort in cases of accident had been made to reduce the period of convalescence by means of mechanotherapeutics, massage, and the other methods known to surgery. The merits of the German workingman's insurance were that it included practically everybody needing insurance; it afforded the workingman the most comprehensive provision, not only in money, but in free medical aid, free medicines, and board in institutions. After an accident or death it offered the surest and cheapest system of compensation, avoiding expensive and tedious litigation. Out of the funds of the country after a liberal payment of indemnities, $100,000,000 had been applied to the erection of model workingmen's houses, sanatoriums, hospitals, and health resorts. In round numbers, eleven and one-half million of people were insured against sickness, eighteen million against accident, and fourteen million against invalidity and old age. In this country the number of industrial accidents was appalling. Dr. Josiah Strong estimated that 550,000 were killed annually in the army of labor. This was 50 per cent. more than all killed in the Russo-Japanese war. In this country

the burden entailed by industrial accidents was borne entirely by the worker. Even if he recovered from an accident he might be incapacitated and have to accept lower wages. In case of accident, compensation had to be paid, even though the negligence was on the part of the workman, unless the accident was caused purposely. The compensation began 13 weeks after the accident, the sick fund or employer being responsible meanwhile. There were no legal expenses or delay. The employer's accident insurance corporation paid out the money through the nearest post office. The cost of administration in the compulsory insurance was only 13 per cent., while in competitive companies in this country 68 per cent. of the premiums were eaten up in expenses. It was highly important that a national association for the study and promotion of compulsory insurance should be formed.

Mr. Sherman, formerly State Commissioner of Labor, said that the number of accidents reported in factories for the year 1907 was about 19,000; of these between 4,000 and 5,000 were either permanently injured, or reported to be so seriously injured as to be practically permanently crippled. About 90 per cent. of all the accidents occurring in factories were in men. In the factories of the State of New York there were approximately 3,600 to 4,000 people, who were efficient and industrious, suddenly thrown out of work and who were to be found among the ranks of the cripples. The law made no provision for their care or support, and they were turned over to public charity. The law that existed in this State was the old common law of England. Under this law the employer must provide a proper place for the employee to work in, and the employee assumed all ordinary risks of the business, the employer being liable only when accidents occurred through negligence on his part. There was a certain unreasonableness in this, as shown when an accident occurred in a factory which was the result of negligence of neither party. When a gang of men was employed, and an accident occurred, it was very seldom that the person negligent was the person injured. Therefore, the person injured in such a case could not sue his employer, because the employer was not negligent. Again, it was the jury who determined what was meant by negligence and who assessed damages, and they, as all know, were influenced largely by their sympathies and not by the real facts alone. If an employee was injured and sued his employer, litigation continued for years, and it was a gamble whether the injured party got anything. Sixty per cent. of the time of the courts was taken up by these cases, and the taxpayer had to spend millions of dollars for the legal machinery. If the injured party won his suit, after the expense of litigation and the attorneys had been paid, the employee would probably get about 20 per cent. of the amount of damages, a very unjust system. In Europe they had abandoned all such laws; the fundamental principle of the system there now was that the industry should pay the costs of the injured, and not have the cost thrown upon the workman and public charity. This was a subject that should be taken up and inquired into carefully. The adaptation of the system as it existed in Europe might be adopted here, and then all classes of cripples would be well provided for and the money not wasted in litigation.

Dr. Virgil P. Gibney believed that the best way to prepare the cripples for usefulness in life was to secure for them proper and useful limbs; this was what the Hospital for the Ruptured and Crippled stood for. Patients were kept there long enough to give them the best possible use of their limbs. Besides attending to their physical defects, they had a very good public school system, as well as singing classes. They also maintained an industrial school. They endeavored to bring out every possible good phase of the child's character that would result in usefulness in his after life. Many of the patients who had been in the institutions years ago were now useful members of society and in business.

Dr. Theodore C. Janeway believed that the thing to be aimed at was prevention, and that curative measures should be a secondary consideration. One might become a cripple as the result of an accident, or from disease, and the preventive measures applicable to the one were not applicable to the other. In the case of the one, prompt and efficient surgical treatment would do away with a large amount of the disability. This could not always be applied in the case of the disease. There would remain, however, many permanently crippled from both accident and disease, no matter what preventive measures were employed. There were the border line cases, those who were only partially crippled, those who had a certain degree of ability to work; these were the ones who needed looking after, in order that they should not become public or private charges. To be useful, industrial training required a preliminary scientific research into the industrial possibilities of cripples of particular types. It should be pointed out to those persons who were responsible for the education of such children that, if the training was to be of value to the individual and to the community, certain lines should be taken up in which opportunities were numerous, in order to assure them of self-support when they left the institution.

Miss Perry of Boston told of the progress which had been made in the school for cripples in Boston in which she was interested. The mental work required corresponded to what was required in the public schools there. In the manual training departments they were taught printing, basket making, sewing, caning chairs, making boxes, etc.

Dr. Thorndike of Boston said that just outside of Boston was the State Hospital for Cripples, which had been in existence for one year; it was under State government. The number of children was 100, many of them with tuberculous bone and joint diseases. Before retiring, the clothing was warmed; then the shacks were thrown wide open. They had wide open school rooms, which were kept open during the day. It seemed to him that the gain in health was almost phenomenal because of this change. Outdoor employments, such as farming, gardening, etc., were taught.

Dr. Wallace said that in one year 6,082 new patients were treated in the outdoor department of the Hospital for the Ruptured and Crippled, and he thought that there might be as many as 7,000 crippled children of school age in New York City. Last year they discharged from this institution 571 children, but he did not know what had become of them. In ten different schools in this city he found 571 crippled children. Among the things to be considered in the care of crippled children were transportation, food, manual and mental training.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

220th Regular Meeting, Held Friday, January 8, 1909.

Dr. E. G. Janeway in the Chair.

Pulsating Tumor of the Forehead.—Dr. W. B. James presented a young man who had for some time suffered from a number of symptoms that were usually included under the term neurasthenia. He complained of headache, vertigo, roaring in the ears, inability to concentrate his mind upon his work, and sleeplessness. Physical examination showed him to be quite sound in body, with the exception of a peculiar pulsating swelling that was situated in the middle of his forehead just below the hair line. This swelling appeared to be vascular in character being supplied by two temporal vessels and one that ran toward the root of the nose; it gave the sensation of

fluctuation, and the stethoscope showed the existence of a continuous murmur produced by the blood current in its interior. Röntgenological examination showed that the skull was intact. A study of the blood supply of the swelling conducted by means of tracings showed the rôle played by the two temporal and the nasal vessels in its production; the obliteration of these vessels by compression resulted in the reduction of pulsation, which fact was well demonstrated by the fall in the height of the tracing produced. However, the obliteration of all three vessels did not lead to the disappearance of the pulsation in the swelling, so that further blood supply in addition to the vessels mentioned above had to be presupposed. It was apparent that this blood supply was derived from some intracranial vessels, and the disturbances of sensation complained of by the patient were probably due to the existence of such communication between the swelling and the cavity of the cranium. Dr. James said that he would like to hear the opinion of the members present in regard to the nature of the swelling and the best way of dealing with it, so as to free the patient from the troublesome symptoms that made his life miserable. As a temporary measure he has advised the patient to sleep with his head raised; this procedure resulted in marked alleviation of the symptoms.

Dr. Charles A. Dana said that he saw the young man on a previous occasion and immediately recognized that his trouble was due to a vascular disturbance and not to a nervous one. Not very long ago he saw another patient suffering from a similar affection: in this case the symptoms seemed to originate not only in the head, but also elsewhere in the trunk, for the patient complained of abdominal pulsations, etc. The patient finally consented to have his carotid arteries tied, and this operation afforded a great deal of relief. Dr. Dana saw him two years after the operation and found him feeling much better, though some symptoms, such as throbbing in the head, were still present.

Dr. A. A. Smith said that the case presented by Dr James could not be benefited by any form of medical treatment; surgery alone offered to the patient some hope of alleviation of the unpleasant symptoms from which he suffered.

Dr. Abbe considered the case to be one of a cirsoid aneurysm of unusual type and location. Surgery offered very distinct hope to the patient, as excision of such aneurysms is both practical and safe. The dilated vessels could be cut down upon and ligated en masse, or the arteries supplying the aneurysm could be tied off one by one. It was quite probable that if the arterial supply of the aneurysm was cut off the symptoms might disappear, or at least be markedly diminished because of the diminution of the venous return, which was probably in great part responsible for the unpleasant sensations experienced by the patient.

Dr. James said that in his opinion the case was one of a Rankenangioma described quite fully by German authors; the arteriovenous communication existing in such tumors led to the production of the sounds heard over the tumor and was responsible for the sensations described by the patient. In his opinion the condition was to be looked upon as a very serious one, and the patient must be told that the best remedy was to remove the mass before it had much chance of increasing in size. Dr. James had seen a case in the Presbyterian Hospital which was somewhat similar in character, though the involvement of the vessels must have been more extensive, as the patient was suffering from a pulsating exophthalmos in addition to the throbbing mass on the forehead. Six operations were performed in that case and yet only a partial relief from the symptoms resulted from the extensive surgical interference. Dr. James thought that in the case presented by him the wisest procedure would be to ligate the two temporal vessels supplying the tumor as a preliminary procedure and then, after the pulsating mass had been reduced in size somewhat by the loss of a part of its blood supply, to remove the remaining network of dilated vessels.

Aneurysm Treated by the Matas Method.—Dr. Robert Abbe showed a colored patient who came to St. Luke's Hospital a few weeks ago suffering from an aneurysmal dilatation of the femoral artery situated just below the profunda branch of the vessel. Dr. Abbe treated this patient by the method recently elaborated by Matas of New Orleans, which offered great advantages over the old method of tying off the artery above the aneurysm, thus stopping all the blood supply below that point. In this case the sac was split open and carefully cleared of clots. Then a tube was made for the blood by diminishing the lumen of the sac, and communication between the artery above and below the dilatation was thus reestablished. On the third day after the operation the arteries below the seat of the aneurysm began to show pulsation, although previous to the operation no pulsation could be felt in them, because the aneurysm took up the impulse of the pulse wave as it came from the heart. For a few days the arteries seemed somewhat shrunken, but they gradually reassumed their normal size, and the part below the seat of the former aneurysmal dilatation did not suffer at all in nutrition. The great advantage of this method of treating aneurysmal dilatation of arteries lay in obviating the danger of gangrene that had often occurred after simple ligation of the aneurysmal sac. The method of Matas not only removed the aneurysm but also restored the circulation, and in this respect it could be called a perfect operation. Dr. Abbe had tried the same method in two other cases, and in both of them had obtained brilliant results. The technique of the procedure was somewhat difficult, the speaker said, as it required the use of very fine needles and sutures, but the result of a successful operation was certainly very much more satisfactory than that obtainable by the employment of any other method.

Dr. James said that the result obtained by Dr. Abbe in this case was most admirable, being more satisfactory than in any other instance that Dr. James could recall. The technique described by Dr. Abbe was, of course, applicable to all aneurysms not affecting vessels situated in the body cavities. If it proved to be applicable even in the latter locations it would mark a great advance in our treatment of intraabdominal aneurysms affecting, for instance, the iliac arteries. Dr. James quite agreed with Dr. Abbe in calling the method of Matas the perfect operation, for it reestablished function while doing away with the anatomical changes produced by the aneurysmal dilatation of the artery.

Transplantation of Teratoma into Monkeys.—Dr. Flexner spoke of a partly successful attempt made by his assistant, N. Jobling, to implant a tumor removed from a human being into monkeys. The tumor was an ovarian teratoma showing the usual structure of such neoplasms and containing a connective-tissue stroma, a great deal of epithelium and some cartilaginous tissue. The tumor recurred after first removal, which was performed by Dr. McCosh at the Presbyterian Hospital, but there was reason to believe that the recurrence was due not to *malignant* infiltration of the surrounding tissue by the tumor cells, but to an implantation of some of the tumor tissue into surrounding tissues, an accident that might have occurred during the operation. The first attempt to transplant the tumor was made after the first recurrence, the material used being obtained at the second operation. Pieces of the tumor tissue were implantd into the subcutaneous tissue of monkeys, and the size of these small bits of foreign tissue was measured from day to day. It was shown that

the implanted bits increased in size for the first sixteen days, then began to diminish very gradually, and finally disappeared altogether. At the time of the maximum size of these bits of tissue, parts of them were excised for a microscopical examination, which showed that no growth of the epithelial constituents of the tumor had taken place at all, the epithelial portion present in the bits of tumor tissue disappearing altogether. On the other hand, the cartilage showed some changes that were quite significant, for mitotic figures testifying to growth of the tissue were found.

On the whole, however, the experiment was a failure, the tumor tissue being finally absorbed. Ehrlich had similar experience after transplanting the tumors of mice into rats; the transplanted bits of tissue persisted for a time, but finally were completely absorbed. It could, therefore, be said, so far as the tumors of lower animals were concerned, that the transplantation of such tumors was possible only when very closely connected species of animals are used in the experiments. The tumor mentioned above recurred once more after the second operation and the attempt to transplant it into monkeys was repeated. The reaction in this case was quite different from that obtained in the first transplantation, both new monkeys and the old animals in whom the first transplantation was made being used for the experiment. In the new animals nothing noteworthy seemed to have occurred, for the bits of tumor were quickly absorbed. In the animals that had previously been inoculated with the tumor the transplanted tissue appeared to have increased rapidly in size. These pieces were removed for microscopical examination and it was then seen that the increase in size was only apparent, being due for the greater part to the formation of a sterile exudate about the foreign material. On the other hand, the epithelial portions of the tumor were not absorbed in this case, but retained the original size. Unfortunately, however, no cartilage seemed to have been included in the pieces used for transplantation, so that it was impossible to find out whether growth would have taken place in this tissue after the animals had been inoculated for the second time. The reaction that had taken place in these animals could be interpreted simply as an anaphylactic phenomenon, the susceptibility of the animals being increased by the primary inoculation. In answer to a question, Dr. Flexner said that it would have been of interest to transplant such ovarian tumors into the ovaries of monkeys instead of using the subcutaneous tissues. At first, however, it was felt that observation of the transplanted pieces could be very instructive and that is why the method used was adopted. Another advantageous experiment would consist in attempting transplantation into the higher anthropoid apes instead of the lower monkeys for inoculation, so as to obviate as much as possible the biological differences between the two species of animals used.

Multiple Pulmonary Abscesses of Obscure Origin.—Dr. Lewis A. Conner reported the case of a girl, twenty years of age, who, two weeks before admission to the New York Hospital, in October, 1908, had begun to suffer from headache and pains in the back and legs, accompanied with some fever. At the end of a week her symptoms grew suddenly worse, and there were added pain in the right chest, cough and increasing fever. She continued to have these symptoms while in the hospital. The fever ran an irregular and very high course, once reaching 107° F.; there were occasional chills, the sputum was abundant, purulent and of rather offensive odor, and the patient was evidently gravely ill.

The physical examination on admission showed an area of dullness at the right base posteriorly, with friction sounds and fine râles in this area and at the base of the right axilla. There were also scattered râles over both upper lobes in front. At that time examination of the heart revealed only some diminution of the heart sounds and a rapid rhythm. Three days later, however, the heart sounds in the region of the sternum took on a curious, loud, amphoric quality suggestive of a pneumo-hydropericardium. This amphoric quality was not heard, however, beyond the limits of the sternum, and at the apex the heart sounds had their normal quality. At the same time it was noticed that the normal heart dulness beneath the sternum had been replaced by a deep, tympanitic note and that the heart seemed displaced to the left. About the same time a small area of consolidation became manifest in the right upper lobe anteriority near the inner end of the second and third ribs; the signs of consolidation at the right base became more distinct, and many moist râles were to be heard over various portions of both lungs. The sputum contained no tubercle bacilli, and Von Pirquet's tuberculin test was negative. Two blood cultures also were negative. At the time of the patient's admission to the hospital the leucocytes numbered 8,000, of which 74 per cent. were polynuclear cells. Toward the end of the illness the white cells rose to 19,000 and the polynuclears to 88 per cent.

The evidence of multiple lesions in the lungs and the abundant purulent sputum suggested the possibility of multiple septic infarcts and the tympanitic note beenath the sternum, and the amphoric heart sounds in that region seemed best explained upon the assumption that one of these suppurating areas had perforated into the anterior mediastinum. Against this view, however, was the fact that no emphysema could be found in the subcutaneous tissues at the root of the neck. Moreover, a careful search of the pelvis, abdomen and veins of the extremities revealed no source for such septic infarcts. The patient died eight days after admission, and during the last two or three days of life the heart sounds lost their amphoric quality. The history obtained at the time of admission did not throw any light upon the perplexing features of the case, but later it was ascertained that during the first few days of her illness the patient had been given by her physician some powders which had frequently excited vomiting. She had persevered in the use of the powders and had vomited repeatedly over a period of several days. It was at the end of this period that the severe pulmonary symptoms had appeared and she had been brought to the hospital.

The post-mortem examination showed the right lung studded with many abscesses, varying from one to three c.m. in diameter. Most of these were scattered through the peripheral portions of the lower lobe; a few occurred in the upper lobe, and one abscess was found in the upper lobe of the left lung. A number of the abscesses had extended to the surface of the lung and had set up a purulent inflammation of the pleura in the neighborhood. One abscess near the median surface of the right upper lobe had perforated into the anterior mediastinum through an opening nearly 1 c.m. in diameter. The mediastinum contained a considerable quantity of pus, and must evidently have contained air, although none could be positively demonstrated at autopsy. The heart and the other viscera were essentially normal and furnished no clue to the origin of the lung abscesses. From the distribution of the abscesses, with relation to the bronchi, the many varieties of microorganisms found in the pus and the absence of all other sources, Dr. Elser, the pathologist, was inclined to regard the case as one of aspiration pneumonia followed by rapid necrosis and abscess formation.

In the light of the history of repeated vomiting before the appearance of the pulmonary symptoms it seemed probable that the accidental aspiration of some of the vomited matter had been the cause of the fatal pulmonary complications.

WILLIAMSBURG MEDICAL SOCIETY.

Stated Meeting, Held March 8, 1909.

DR. WILLIAM LINDER IN THE CHAIR.

The Symptomatology and Diagnosis of Pancreatic Disease.—Dr. LEON LOURIA of Brooklyn read this paper. He said that few diseases were so difficult of detection as those of the pancreas, particularly on account of its close juxtaposition to the stomach, duodenum, and gall-bladder, and the close association of its main duct with that of the latter viscus. This association had its physiological significance in the intimate cooperation between the pancreatic juice and the bile in the process of digestion. This was an unfortunate anatomical relationship, and was the cause of many of the morbid processes to which both the pancreas and biliary passages were subject. Another unfortunate anatomical anomaly was the fact that in two-thirds of all cases the common bile duct passed directly through the head of the pancreas on its way to the duodenum. The difficulty of palpating an enlarged pancreas was responsible for the dense obscurity that until recently had veiled all knowledge of the affections of the pancreas. This had slowly emerged in the light of the autopsy room and operating theater. The functions of the pancreas in furnishing both external and internal secretions had to be fully understood for a correct interpretation of its diseases. These were to be considered as not only cause and effect of diseases of contiguous organs, but were also in close physiological relationship with diseases of remote organs, in the evolution of disordered metabolism. The cooperation of surgeon, internest, and laboratory worker was necessary in the investigation of diseases of the pancreas more so than in any other branch of medical research. Little had been recently added to the knowledge of malignant disease and cysts of the pancreas, while the acute forms of pancreatic disease, described by Fitz nearly twenty years, had hardly been added to by more recent writers. The recognition of chronic pancreatitis was the triumph of more recent years, and to the credit of American pathology. It was a form of disease most difficult to recognize and challenged the keenest diagnostic resources of the clinic and laboratory. There were two forms of the disease: interlobular and interacinar. In the latter there was not only atrophy of the secreting cells, but also more or less complete destruction of the islands of Langerhans, which occasioned severe derangements in carbohydrate metabolism. Experimentally, these forms of pancreatitis had been produced by the injection of irritant substances, such as bile, into the pancreatic duct. This explained the frequent coexistence of chronic pancreatitis and cholelithiasis. When the papilla of Vater was occluded by a calculus there was retrojection of bile into the pancreatic duct. The passage or stasis of a stone in the common bile duct often caused necrosis and subsequent infection of the head of the pancreas. This was also caused by occlusion of the pancreatic duct, with the damming back of the pancreatic secretion. There was also close vascular and lymphatic communication between the gall-bladder and the head of the pancreas, so that infections of the former were easily transplanted to the latter. Tuberculosis, syphilis, and arteriosclerosis often involved the pancreas. There was a close association between pancreatitis and mumps. Pressure of the swollen head of the pancreas, which often occurred in this infection, upon the common bile duct, was now considered to be the rational cause of epidemic jaundice. Egdahl considered mumps as the causative factor in 10 per cent. of the cases of pancreatitis. The symptoms of chronic pancreatitis were divided into four categories: first, those due to pressure on the common bile duct; second, those due to diminution in the external secretion of the pancreas; third, those due to impairment of the internal secretions that presided over carbohydrate and fat metabolism; and fourth, those due to the inflammatory process seated in the pancreas. The symptoms referable to pressure on the common bile duct could not be closely differentiated from those due to cholelithiasis. Both conditions caused jaundice, but that due to pancreatitis was more apt to be persistent In addition, there were acholic stools and urobilinuria The symptoms of the second category were the most prominent in the pancreatic syndrome. There was emaciation, which frequently erroneously suggested malignant disease. The stools were offensive and of enormous bulk. There was steatorrhea or the presence of an excessive amount of fat in the stools. More characteristic than this was the diminution in the proportion of split fats. There was also azotorrhea or the presence of a large amount of undigested muscle fibers, and, more important still, the presence of the muscle nuclei, for failure to digest these was a special feature of pancreatic insufficiency. Schmidt's test was designed to determine the presence of muscle nuclei. Sahli's method of testing the efficiency of proteid digestion was next described, as was also Müller's test for determining the degree of tryptic activity of the feces. An important constitutional effect of pancreatic insufficiency was the profound and progressive loss of weight in spite of a rich diet. The symptoms that resulted from defective metabolic activities of the pancreas were not always present, owing to the fact that a small portion of the gland could, if present, preside over the metabolic conversion of sugar and fat. Hyperglycemia and consequent glycosuria frequently occurred, but not in all cases, even of the interstitial variety. Extensive disease of the head and neck of the pancreas was not associated with glycosuria, for the islands of Langerhans were most abundant in the tail of the pancreas. The glands of Brunner in the duodenum were capable of taking in vicariously the metabolic functions of the pancreas. Although the absence of glycosuria did not rule out pancreatitis, yet its presence, particularly in conjunction with jaundice or cholelithiasis, was a sign of no little value. A form of diabetes that could without question be attributed to pancreatitis was the *diabète bronzé*, which was an expression of hemachromatosis in the deposition of blood pigment in the internal organs and in the skin. Its presence in the pancreas set up a chronic interstitial pancreatitis and a consequent diabetes. Certain cases of pancreatitis were associated with disease of the adrenals. Instead of a true diabetes, pancreatitis was frequently the basis of an alimentary glycosuria. The pancreatic reaction of Cammidge belonged to this group of metabolic disturbances. The newest, or the Cammidge "C" reaction, consisted in the isolation from the urine of patients suffering from an inflammatory disease of the pancreas, of a substance which, when boiled with strong hydrochloric acid, split off a body having the chemical character of the sugars. It was a most difficult and laborious method of analysis, but was reliable and of great diagnostic value, although practically unavailable for the average practitioner. Pneumonia, adenitis, and cancer also gave the reaction. Hewlett's reaction consisted in the detection in the urine of lipose, which occurred particularly in cases of acute pancreatitis complicated with fat necrosis. The recent experiments of Lombrosa had shown that an internal secretion of the pancreas enabled the body to consume its own fats. These probably explained the occasional existence of peculiar accumulations of fat on the chest and abdomen in cases of pancreatic disease, resembling in certain respects adiposis dolorosa. The fourth group of

symptoms were due to enlargement of the pancreas and pressure on neighboring structures. Rarely the hypertrophied pancreas could be palpated. There was pain due to inflammation and pressure on the solar plexus, to a neuritis of its pancreatic branches, or to a localized peritonitis. The pain was not agonizing, like that occurring in acute pancreatitis in which there were also shock and severe collapse, with rapid pulse and vomiting. The pain of chronic pancreatitis was either continuous or periodical. Continuous pain was also observed in pancreatic cysts, calculi, and carcinoma. In the last the pain was very severe, and was aggravated by movement. The periodical pain suggested epigastric colic, and similar attacks occurred with renal calculi, appendicitis, and a beginning pericolitis in the region of the splenic flexure. It was difficult to differentiate these attacks of pain from those of gallstone colic, even when there was accompanying jaundice or any of the other symptoms of cholelithiasis, for both conditions frequently coexisted. In gallstone disease the pain was never associated with the extreme weakness observed in pancreatitis. Pancreatic stones also caused attacks of epigastric colic. The character of the pain frequently prompted a diagnosis of nervous gastralgia. In most cases of chronic pancreatitis there were, in addition to the pain, a point of marked tenderness midway between the tip of the ninth rib on the right side and the umbilicus (Robson's point), and an area of tenderness and muscular spasm along the right rectus a little to the right of the umbilicus and extending upward from it for several inches. There was reflex pain referred to the region of the left scapula. These signs were variable and sometimes there was no pain at all, even with extensive lesions of the pancreas. Other and even less characteristic symptoms than the pain were dyspepsia, constipation, vomiting, emaciation, attacks of syncope, hemorrhagic stools, and jaundice. Salivation occasionally occurred as a reflex compensatory activity. The emaciation was progressive and profound. The icterus was frequent and significant. In that which was associated with diseases of the gall-bladder and ducts, the irritation of the skin was apt to be less. The diarrhea of pancreatitis was characterized by large, soft, greasy stools, while the dyspeptic symptoms centered chiefly about the distaste for fats and meat. Ascites was sometimes produced by pressure of the enlarged pancreas upon the portal vein. In conclusion the speaker said that pancreatitis was not a rare disease; it frequently masqueraded under the guise of chronic indigestion, indefinite epigastric colics, and many other vague abdominal manifestations. While internal medication hardly claimed any glory in the successful treatment of pancreatitis, it was the internest who had to appreciate the complex picture of this disease and who was in a position to surrender his patient in time to the surgeon, who alone could afford the only real relief.

Acute Pancreatitis: Symptoms and Treatment.—Dr. John F. Erdmann of New York read this paper. He said that he had previously written that chemical analyses, as then understood in pancreatitis, were frequently misleading, and that symptomatology had to be relied upon to the extent of urging the patient to submit to an exploratory section. He was now willing to withdraw this statement, in view of the successes obtained with the Cammidge "C" reaction, especially in connection with the history and other analyses. This applied to those acute, subacute, and chronic cases in which the time taken for the various analyses did not endanger the patient's chances for an operative recovery, but did not apply to the cases of acute hemorrhagic pancreatitis, with intense onset, or with acute abdominal shock, where the long delay necessitated by the Cammidge reaction jeopardized the patient's life to such an extent as to reduce his operative recovery to almost nothing. In this variety the exploratory operation was necessary to develop a diagnosis. The difficulties of making a diagnosis in the ultraacute stage were multiplied by the contiguity of the pylorus, gall-bladder and its ducts, and the head of the pancreas.

For this reason it was manifestly important that all aids in the chemistry of digestion and the excreta should be called into play. The stools were fatty, were large and spongy, and contained undigested muscle fibers. The urine, in addition to giving the Cammidge reaction, also frequently contained sugar. The speaker alluded to six cases, all without any sugar before or after the onset, one of which was of acute hemorrhagic pancreatitis. The speaker regarded the presence or absence of sugar in acute cases only as a coincidence, and not as a distinct evidence. The lipose reaction required a complex chemical outfit and process, with a period of more than twenty hours' actual preparation, and was not of value in the ultraacute cases. The duct of Wissung was a frequent source of entry of infection; the damming back of bile by a calculus plugging the Vaterian papillus was a common cause; other factors were traumatism, alcoholism, and arteriofibrosis. The cause of death in the acute cases had been attributed by Doberauer to a toxin, and by Guleke, in the acute necrosis cases, to intoxication with trypsin. The speaker reported six cases, four hemorrhagic with two living, and two with abscess formation with one living. Complete destruction of the pancreas occurred in one of the hemorrhagic cases, and its former site was occupied by a blood clot. None of the cases had been accompanied by a slough. The onset of acute pancreatitis was usually a sharp pain, with shock, and rapidly followed in same cases by profound toxemia, denoted by a peculiar cyanosis and lividity, with shallow breathing and rapid pulse. There was especially lividity of the face and abdominal wall. The pain was far more intense than that of gastric perforation or appendicitis. Hiccough was of relative frequency and persistence and vomiting accompanied and followed the pain onset. There was in four of the six cases pain in the back of an intense splitting character. The pain was more severe than that of gallstone colic. These symptoms, with a history of previous digestive disturbances and gall-bladder or duct invasions, were strongly indicative of acute pancreatitis. Fitz's rule was that acute pancreatitis was to be suspected when a previously healthy person, or sufferer from occasional attacks of indigestion, was suddenly seized with violent pain in the epigastrium, followed by vomiting and collapse, and in twenty-four hours by a circumscribed epigastric swelling, tympanitic, or resistant, with slight rise of temperature. The subsequent manifestations were those of an ordinary peritonitis. The treatment was as follows: When in doubt, exploration was to be done. If, upon the latter, there was discovered a peculiar bloody, beef broth-like serum, or peculiar warty, yellowish white plaques of fat necrosis on the omentum or mesentery, search was to be extended to the pancreas. On finding an acutely hemorrhagic, enlarged pancreas, an incision was to be made in its peritoneal coat, and a puncture or punctures in the pancreas itself, and gauze or other drains were to be placed in the incised or punctured areas. In gangrenous or suppurative pancreatitis sufficient drainage was to be provided, either by the anterior route or the costavertebral angle, though the anterior was the better and less dangerous route. The question of doing a cholecystotomy or not was one

that each individual case presented for consideration. The speaker then described the histories of six cases, in three of which the gall-bladder was drained, each time for large numbers of stones. Two of the cholecystotomy cases died and one recovered, while two of the remaining cases recovered. In conclusion, the speaker called attention to some of the pronounced symptoms of acute pancreatitis, which were: The marked pain at the onset, the sharp intoxication, the dyspnea, and lividity, the constant splitting backache, and emphasized the need of early exploration when the given set of symptoms manifested themselves.

Dr. Joshua M. Van Cott of Brooklyn said that the speakers had covered the subject of pancreatitis so well that there was little to be added. The literature of pancreatitis had already assumed enormous proportions. Truehart's treatise on fat necrosis comprised 600 pages. Dr. Louria had brought out beautifully the complex relationships of the pancreas, both in its gross and microscopic aspects, and enabled one to clearly trace the relationship between faulty structure and the semiology of pancreatic diseases. The infrequency of diabetes as a symptom of the latter had been fully explained, for the vulnerable part of the pancreas was not rich in the islands of Langerhaus. The sudden shock occurring in acute pancreatitis had been explained by certain authors as an indication that the solar plexus was the seat of the same condition that prevailed in the pancreas. There was only one thing apparently that the first speaker had not included in his comprehensive presentation of the subject, and that was the theory that fat necrosis might be the result of fat splitting bacteria normally present in the intestinal flora, or to lipolytic enzymes in the blood, or even in the somatic cells. The theory that fibrous degeneration of the pancreas similar to that which occurred in the liver and kidneys might occur in the pancreas found a strong support in the fact that, according to Thoma's blood-pressure scheme, these organs all stood at the same level of blood pressure, namely, about 5 millimeters.

Dr. Walter C. Wood of Brooklyn said that in his surgical service at the Brooklyn Hospital he had found the Cammidge reaction to be reliable, appearing in 80 per cent. of his cases of pancreatitis. It was particularly valuable as a means of differential diagnosis between pancreatitis and malignant disease of the pancreas. One year ago he had read a paper in which he had described four per-acute cases of pancreatitis. There had been no recoveries. Two subacute cases in which there had been abscess formation had both recovered. In these the abscess had drained six weeks. In the presence of an acute pancreatitis one could not wait, but had to make the incisions into the pancreas. There were on record twenty-three cases in which as the result of this procedure a complete recovery had been made. The surgery of chronic pancreatitis had not been mentioned. If there was cholecystitis with gallstones, these had to be removed and the gall-bladder drained for six or eight weeks; these cases made a clean recovery. In the cases of pancreatitis without gallstones, simple drainage of the gall-bladder was not sufficient; it was necessary to drain the gall-bladder into the stomach or intestines. Mayo had described three cases in which the gall bladder had perforated the stomach, with spontaneous recovery. It was theoretically wrong, yet practically sound, to perform an anastomosis between the gall-bladder and the stomach. The ideal forms of anastomosis were with the duodenum, or, still better, the jejunum. Anastomosis with the transverse colon was theoretically wrong, owing to the possibility of the ascension of bacterial infection from the latter, yet it was successful as a practical procedure. As a means of distinguishing with the naked eye between a chronic inflammation of the head of the pancreas and malignant disease of the latter, it was to be noted that in chronic inflammation the surface was usually smooth, while in malignant disease it was nodular.

Dr. H. Beeckman Delatour of Brooklyn said that he had been impressed by the peculiar cyanosis and extreme collapse of acute pancreatitis. The pain was sometimes deep in the abdomen, and was sometimes referred to the back. He cited one case in which there was vomiting with persistent hiccough. There was also one case with attacks resembling biliary colic, with gradually increasing jaundice. He also cited a case of chronic pancreatitis complicating cholelithiasis, in which the head of the pancreas was nodular, simulating carcinoma.

Summer Course of Ophthalmology at Oxford.—The sixth annual course in the department of ophthalmology of the University of Oxford will begin on Monday, July 5, and terminate on Friday, July 16. The main idea of the course is to demonstrate on actual patients, as far as possible, the whole range of ophthalmology, in order to make the reading of a text-book more profitable than can be the case when reliance has to be placed on pictures alone. The first part of the course will be concerned mainly with the practical examination of eye patients, the use of the ophthalmoscope, and the estimation of refraction. During the second part the work will be more specialized and the lectures will be delivered by various ophthalmic surgeons. As on previous occasions, the last two days will be devoted to addresses, special demonstrations, and the examination of interesting and unusual cases. The fee for the course is five guineas. Further particulars can be obtained from Mr. Robert Doyne, M.A., F.R.C.S., Margaret Ogilvie reader in ophthalmology in the University of Oxford, 30 Cavendish square, London, W.

Occlusion of the Abdominal Aorta. The patient of C. H. Cattlewas, a man of 39 years, was admitted to hospital for palpitation, dyspnea, and precordial pain. He had presystolic heart murmur, but no dropsy, and no symptoms referable to lungs, liver, or kidneys. In the course of a few weeks both lower limbs suddenly became paralyzed, and no pulsation could be detected in the femorals or vessels below. Urine contained much blood. The man died almost three days later with hiccough and profuse sweating. No autopsy was obtained, but, from the loss of motion and sensation in the legs, with the other symptoms, no doubt was felt as to the existence of an aortic occlusion. The clot presumably reached as high as the renal arteries. The author says that valvular disease of the heart, especially mitral stenosis, is a fruitful source of embolism, hence it is natural to suppose that embolism of the aorta should occur in the same circumstances as embolism of smaller arteries. The large size of the aorta raises the doubt whether any embolus could be sufficiently large to completely plug it. But an embolus frequently grows in size by the formation of thrombus around it and therefore an embolus arrested at the bifurcation of the aorta might be enlarged in this manner until it filled the lumen of the vessel and extended into both iliacs. An attack of pain in the right iliac region which this patient experienced a few days before the final attack may have been due to a similar cause whether embolism or thrombosis. The occlusion in this instance cannot have been complete, as the symptoms associated with it abated, yet it seems not improbable that an embolus was carried into the right internal iliac still allowing the circulation to be carried on for a time, and that by gradually extending upwards it eventually caused the obstruction of the aorta. Moreover, mitral stenosis not only provides a possible source of embolus, but also often leads to very low arterial blood pressure, which itself is a cause of spontaneous clotting in the vessels. In this patient compensation had quite broken down and it was found impossible by means of rest and cardiac tonics to restore regularity to the pulse or tone to the heart. Hence the circulation was inefficiently maintained, the propulsive force being weak and intermittent. Under these conditions thrombi might be formed in the left cavities of the heart and be the source of an embolus.—*The Lancet*

THE POINT OF VIEW IN MEDICINE.*

BY BEVERLEY ROBINSON, M.D.,

NEW YORK.

I TAKE it that few among us look at medical questions, at present, as we once did. Youth and inexperience never look at things quite in the same way that older and usually, I trust, wiser heads do. Again, the general practitioner has his standpoint, which will frequently differ from that of the general surgeon, or the specialist of one kind or another, almost of necessity. The specialist on his side, and more than ever perhaps to-day, considers, or appears to, that his view of the case is the true and the really advanced one. Now, general practitioner, general surgeon, specialist, are all somewhat influenced by the spirit of the age, surroundings, atmosphere in which they move and live, education, and, despite everything, personal idiosyncracy of their own. Some men are talented, earnest, hard-working, of large experience, and yet they never seem to take quite the same view that others do, even among their peers. Are they right and the majority wrong? It would be unsafe to admit the rule. What we can say with truth and justice, however, is that there are men—a few, a very few—who to skill, experience, training, study, all of the best, add a similar fund of common sense, of mental just balance, so to speak, rectitude of thought and purpose, which makes them think straight, and almost invariably reach sane conclusions, the best practically there are in regard to diagnosis, prognosis, and treatment. So clear and cool are their perceptions, so well balanced and considered their arguments, so free are they of all "fads" or "fancies," that having heard them express a judgment about a case usually leaves in our minds a very strong impression, a tendency almost to share their views, despite perhaps our own which are sometimes opposed to them.

We all know a few such men in our profession and we are grateful for their possession. I shall not speak of men still living, but I shall mention a few I have known or under whom I have studied; and these men will ever remain to me beacon lights of what is best, wisest, truest in medicine and surgery, in which, properly understood, are included, as I believe, the highest ideals given to man to attain on earth. In the list I would include as physicians Jenner, Trousseau, Meigs, Da Costa, Flint, as surgeons, Nélaton, Ferguson, Parker, Agnew, Sands, Bull. I leave to others to mention specialists who may and should rank with these men of great mind, great heart, great courage.

Some of us have never been able quite to get away from the powerful influence of the recognition of a constitutional condition—dyscrasia—in almost every disease, acute or chronic. We cannot see a local affection of any sort, with relatively few exceptions, apart from it. And therefore it is that we are inclined more to general treatment, if any, rather than to local means of help or betterment. To a certain extent, no doubt, this view depends upon our previous and early medical education. Those who have imbued French ideas believe in them perhaps overmuch and see a diathesis almost in every patient. On the other hand, the physicians whose early training was in Germany, in Vienna or Berlin, localize agencies overmuch, and adopt local treatment to the exclusion, at times, of general remedies, because they were taught that in local means could be found the best, if not the sole curative agents.

Formerly, surgery could not and would not perform many operations, by reason of the excessive mortality, which now are performed daily and with very little risk to life in many instances. The physicians of the present time admit great advances in surgical technique, and praise and laud it whenever they feel it proper so to do. On the other hand, they feel, and indeed believe they know, that operations, no matter how skilfully performed and with what remarkable immediate outcome, do not invariably lead to apparent good results. They see recurrences, they remark unexpected deaths, they are not unfamiliar with painful symptoms later, which are fairly attributable to previous operations. Again, they believe, with more careful, painstaking diagnoses, with insistence on correct methods of living—better food, less strenuous life, purer air, prevention of disorders in time, by suitable, well considered medication, many operations might be avoided. Further, they ask, *cui bono*, to have an operation successfully performed and to return to the life and conditions which were unquestionably the occasion of the development of the disease primarily, and which led to the necessity of an operation.

Physical methods of research, even those most employed—namely, palpation, percussion, auscultation, mensuration—are surely very valuable; but, after all, do they teach the vital questions, do they explain frequently why and how we have disordered function, do they enable us always, or indeed in the majority of instances, by themselves, to meet the indications of successful treatment? The newer laboratory methods which give us all we know about blood, stomachal contents, intestinal excreta, do they always ring true when it is a question of how to medicate or treat the patient, even from a surgical standpoint?

A few years ago, a rapidly increasing leucocytosis with acute abdominal pain and tenderness, with or without rigidity, it might be, would have

*Read before the Practitioners' Society of New York March 5, 1909.

seemed to indicate appendicitis and operation. Now we know that leucocytosis, developing rapidly, and acute abdominal pain may find their anatomical seat in the lungs, and a few hours or days later be shown to be due to fibrinous pneumonia. Test meals of a roll and tea, without milk or sugar, do not seem to bring out rationally the best that may be known as to stomachal fluids and the powers of digestion. Good cooking, foods properly prepared and served, will not infrequently settle the questions satisfactorily to the experienced old-time practitioner, when all the refined later wisdom of the laboratory helps us very little, or not at all.

Only a month ago I had a letter from a gentleman whose wife had a diagnosis of ulcer of the stomach, made by two stomach specialists, widely known and in whom the wisest treatment of so-called science was carried out. The result was negative. Subsequently, a very simple treatment, merely the result of wise empiricism, gave a brilliant success. No doubt the laboratory explanation of the happy cure will come later.

In diphtheria I have known the Löffler bacillus not to be correctly found with good microscope and good observer, or else to be very inoffensive so far as causing disquieting symptoms was concerned. Again, I have known a case in which diphtheria was never made out in the best appointed laboratory, and yet when symptoms were most threatening and gravest, life was saved only with proper use of antitoxin.

All this doesn't mean to invalidate laboratory work at proper time and place, and duly and rightly interpreted, but it does mean to reaffirm the conviction on the part of many of us to-day, that laboratory must usually be subservient to older and more reliable clinical methods, if we are to obtain from them what we should require—not as rulers, but as handmaids.

Even in surgical diseases, as witness cases of malignant trouble of the breast or elsewhere, so diagnosed by the laboratory, there are instances, as Maurice H. Richardson has lately stated, in which the clinical acumen of the wise, experienced surgeon may recognize, truthfully, that the prognosis is good and eventually the disease will prove not to be cancerous.

Take now the work of the dead house, and where are we? Where should we be? The pathologist sees in every visible change of structure or organ the great kernel of truth, as it were; the one thing which explains symptoms, suffering, death. Is he right? At times, yes; many times, alas, all wrong, as I believe. No doubt, in pathology, in autopsies, may be found our surest guide, in the main, to securing accurate knowledge of what is in one way a basis for thorough and satisfactory knowledge of our science. But apart from science, there is the art of medicine, which is practice, and this is most important, as you and I know, and is not based solely upon knowledge from the dead house.

I have been witness of, or made, autopsies in which the body was full of organic lesions, and yet during life there had been little pain or suffering or disability of any notable kind, during many years prior to death. Again, we may have one who while living had suffered almost continuously from various ailments, and yet his body at the autopsy was almost or entirely negative, so far as visible pathological lesions were concerned, and as explaining clearly previous suffering or death itself.

Despite all our vaunted and great advance in research, much is still unrevealed, much is still, by reason of ignorance, no doubt, *functional,* so far as we can state positively. But such an affirmation should not for a moment, from a healthy, sane standpoint, in my judgment, give a shadow of right and justice to religious health healers—such as, alas, we meet to-day in the so-called curists of the Emmanuel type. Physicians are after all the true and only ones to look after the needs of the body, and when mental comfort is required, physicians of the best type are often better able to give it than the theologians. Every good and true physician is to-day rejoiced at the probable outcome of the great antituberculosis fight being waged, and while it must be very useful in diminishing the number of those who are thus affected with a dread disease, it is even to a wider degree beneficial, because success in the fight means progress in civilization, refinement, and healthful living for all men. But I see an evil ahead, already referred to by a few. In our efforts to get rid of tuberculosis, so praiseworthy and encouraging, let us not insist upon foolish rules of prevention or cure, and thus become absolutely cruel to those who most urgently require our sympathy and real, genuine help and support.

Bear in mind the following true and important statement of the Health Board of the State of Massachusetts: "It is not at all uncommon to-day to hear of instances where the very means of obtaining one's livelihood have been taken away because the person was unfortunate enough to have tuberculosis. To take away from such a person the means of obtaining his livelihood is to take it from the very person who needs it most. It should be remembered that a person ill with tuberculosis, whose personal habits are clean and who takes care of the material which he coughs up, is a safe person to live with, and that he may attend to his work without endangering his fellow workmen. Failure to appreciate this fact is already causing many hardships, which are both unnecessary and unjust."

These are words of gold, and should be distributed far and wide. Only a short time ago, I knew of an instance where a young man, an only son, was practically driven from place to place, even in a healthful country region, simply because no hotel or boarding house would harbor him for fear of infection. Foolish and inhumane to the highest degree!

Again, while several hundred papers were read at the late International Tuberculosis Congress, in Washington, there was not a single one, so far as I know, devoted to the medicinal treatment of the disease. Is not this lamentable, though true? If there were no medicinal treatment of any avail, it would be equally sad and deplorable, but it would be excusable. But there is a medicinal treatment of the highest value, in my judgment, and, as ample and sufficient proofs have been given of its efficacy, it does seem almost incredible that it should not be widely known and adopted.

It is probable that very few men of judgment and experience believe that pulmonary, or other form of tuberculosis, is cured solely by any kind of medicinal treatment, but some of us do believe, and firmly, that many die without proper medicinal treatment who would and could be saved if they had it—at the proper time and in the right way. Alas, the pity of it!

There are many other topics I might touch upon

and bring about a profitable and instructive discussion from members of the society, and I would very much like to have such a discussion at a later meeting. One topic would be alcoholism; the other prostitution. I, for one, believe that we shall never limit the great, immense evils of alcoholism, until we greatly diminish the custom of treating, or round drinking. I believe, also, we cannot hope to diminish the immense evils of prostitution and the frightful diseases which are its direct outcome, unless it be systematically and carefully governed and regulated, and not merely ignored, or considered as being radically bad, and therefore to be stamped out. It cannot be stamped out entirely—certainly not in large centers of population. The history of the world proves it. Therefore, let us do the best we can to lighten the burden of it, to working, decent men and women, who wish only what is best in last resort, for the betterment of the human race.

In finishing these brief, very imperfect remarks, no one could be more conscious than I of their discursiveness and superficiality. At the same time, they will, I hope, lead to an interesting and profitable discussion—and that will surely be valuable. They could be readily lengthened, amplified, but I don't care to bore or tire you.

A few last words. We have learned from homeopathy some truths despite its great and sinning errors. One is, as I believe, to try and relieve, correct, it may be, symptoms of disease carefully, intelligently. Not to the extent of ignorant assumption, as formerly—not to the degree, for a single instance, of throwing aside true science based upon accurate, advanced research, in hospital ward, dead house, laboratory—but only to that extent which should, which must teach all thinking physicians that man is not a mosaic, composed and stuck together, of small independent parts, but not correlated vitally; that he is not merely an organic mass of blood and tissues, of which the final word comes from chemistry, pathology, physiology, or bacteriology, solely, but that he is a moving, living, vital personality—always alike in a way, but always absolutely different and distinctive—and that he the wisest among us is he also, who alone, finally, should judge and rule, when it is a question as to what line of action—of doing—may or should be followed with best advantage to the patient's ultimate good. Whenever the patient is passed over to the specialist in any line by the general practitioner, the general practitioner should then become and be regarded, *ipso facto,* as the consultant who is best for the patient's good if any consultation is at all required, and simply because he, the general practitioner, the all-round, good and true physician, who has had frequent previous charge of the patient, it may be from his baby days, is the only man who knows all about him and can appreciate at times what is best to do for him—what, in other words, will most surely lead to his ultimate well being and complete recovery, or else to the best results for him possible.

Let me conclude by quoting from Dr. William H. Draper's address, familiar to many of you, and delivered with such marked effect years ago before the Association of American Physicians:

"We may wisely recall and apply the answer," writes Dr. Draper, "which Iphicrates, the Athenian general, is said to have made when he was hard pressed by an orator before the people to say what he was to be so proud: 'Are you a soldier, a captain, an engineer, a spy, a pioneer, a sapper, or a miner?'

"'No,' said Iphicrates, 'I am none of these, but I command them all.'"

"So the practical physician may not be a very learned pathologist, an erudite physiologist, a skilful chemist, or an expert bacteriologist, but he must command them all, and it is he who must finally, through the cooperation of all the sciences which they represent, perfect the most beneficent of all arts; it is he who in his high mission as the servant of humanity must attain that wisdom which results from combining knowledge with the instinct and the skill for its useful application."

THE REEDUCATIONAL TREATMENT OF LOCOMOTOR ATAXIA.*

By J. RALPH JACOBY, M.D.,

NEW YORK.

In the summer of 1908, I had the opportunity of carefully studying the question of the mechanical and reeducational methods employed by Dr. H. S. Frenkel, in the treatment of locomotor ataxia at Heiden, Switzerland. There are a great many elements that enter into the treatment of tabetics at Heiden, the understanding of which is really essential to a more comprehensive insight into the results which Dr. Frenkel obtains.

Heiden is a picturesque little village situated on the top of a hill overlooking the Lake of Constance. The place itself has been regarded as a health resort for years, on account of its altitude, and consists for the most part of small hotels with their so-called dependances and boarding houses, so that it is safe to say that the 2,000 inhabitants depend upon the visitors for their livelihood. The patient is catered to in every way possible by the villagers, while the town itself has provided walks and drives, as well as a Kurgarten, which makes Heiden very similar to the many other health resorts to be found in Switzerland. One of the hotels has been equipped with hydrotherapeutic baths, and directly opposite, in a grove of trees, is the gymnasium.

The patients then take up their abode, according to their means, in one of the hotels or boarding houses, none of which is more remote than five minutes' walk from the gymnasium. The whole environment, the absence of distracting influences, the facilities for comfort and care, all contribute to the patients' well-being, to such an extent that it materially aids in their ultimate improvement.

Before proceeding, permit me to recapitulate a few of the fundamental principles that underly the whole system of reeducation, in the treatment of tabes. The reeducational treatment deals solely with the symptoms of the disturbances of coordination. Frenkel starts with the theory that in tabes, the ataxia is dependent upon sensory disturbances in the muscles and in the joints. If, therefore, the muscular sensibility and the joint sensibility are completely destroyed, there will be no coordination possible. The first essential then is to determine how much muscle and joint sensation has been preserved, for it is upon this remnant of sensibility that the efforts are directed. The unimpaired sensibility, no matter how small, is utilized and educated until it reaches a stage of sufficient acuteness, so that a new system of coordination has been established. Most primitive methods are first used. It

*Read before the Section of Neurology and Psychiatry at the New York Academy of Medicine March 8, 1909

is necessary to begin at the bottom and work up, and this is accomplished through the constant repetition of certain well-chosen and necessary movements, that call into action the very minimum of muscular strength. It is most essential, therefore, to understand down to the smallest detail the mechanics of the various groups of muscles.

Movements of apparent simplicity are in reality very complex when analyzed into their component elements, and Frenkel has made these analyses so carefully that he has been able to formulate exercises that range from the simplest, which involve the use of only one or two muscles, to the most complicated, which cause the muscles of an entire extremity to be brought into action.

In this connection can be seen the extreme importance of dividing the treatment of the disturbances of coordination of the lower extremities into two parts: the bed exercises and the walking exercises. In the bed exercises, the patient lies on his back and his legs are free to move without the weight of his body. Each leg can be exercised separately, or in harmony with the other, or exercises diametrically opposite can be executed with both legs at the same time. In the upright position, however, all the muscles of equilibrium are brought into play, so that any additional movement, no matter how simple, is still very complicated. But here again the understanding of the mechanics of various movements is necessary. It is wonderful to see how a helpless patient, in the course of ten or fifteen minutes' instruction, merely by the correct and properly directed use of his muscles, can accomplish movements that hitherto have been practically impossible to him.

By means of these oft-repeated instructions and constant repetition of the exercises, the reeducation of the muscles is accomplished. It is no trick, but requires an inordinate amount of patience at times.

In all these exercises, the eyes play a prominent part. In the beginning, when the patient's muscular and joint sensations are obtuse, it is difficult for him to locate the position of an extremity without looking at it, so that all of the exercises are first instituted with the patient's eyes closely following each movement. By degrees the exercises are repeated while the eyes are directed elsewhere, until finally the eyes are excluded entirely by closing them. Thus we have a progressive gradation in the education of the muscles.

This brings us up to that important problem, the question of dosage. It is well known that tabetics are to a great extent insensible to feelings of exhaustion. Overtaxation does not tire them as it does a normal person, and for this reason one cannot be governed by the patient's subjective feelings. Dr. Frenkel uses the frequency of the pulse as an indication of the patient's condition. In many cases I have seen the pulse, which normally was between 70 and 80, rise rapidly to 110 and 120 after the exercises, and in some cases as high as 140, without the patient experiencing any feeling of fatigue. In the bed exercises the pulse does not rise so rapidly, but Frenkel never exceeds 10 minutes in these exercises, and at the same time he allows the patient frequent periods of rest during the treatment. In the walking exercises, however, the variations of the pulse are more apparent. As soon as the pulse shows any sign of the patient's fatigue, the exercises are discontinued. The general time consumed in the gymnasium is about ½ hour, but during this period the patient rests half of the time.

In the education of the patients in the gymnasium, practically no apparatus is used. With the exception of a constructed staircase on which the patient is taught to go up and down stairs, the only aid used is a series of markings on the floor. The hall is about 15 meters long and on the floor are marked transverse lines that can be distinctly seen, and the distances between these lines represent variously what Frenkel terms ¼, ½, ¾, and full steps. On these limited spaces the patient is taught to walk his measured step, which is varied from time to time in length and rhythm. Variations of equilibrium are effected by placing the arms in different positions. Frenkel decries the use of gymnastic apparatus, whether simple or complicated. He reiterates that the reeducational treatment is to *educate* muscles, not to strengthen them. The muscles generally, in tabetics, are sufficiently strong and well developed, in fact the muscleplay is always very much in excess of the actual force required to effect any desired movement. The use of weights and appliances, Frenkel maintains, can seriously injure the patient as it subjects him to a strain that not only exhausts the muscle fibers, but dulls the remaining sensibility inherent in the muscle itself. The theory that if a person must jump five feet, he should try to jump ten, does not hold good in the reeducational treatment. Nothing more should be required of the patient than is actually necessary to accomplish any particular movement. And it is for this reason that the exercises are so carefully graded.

The difference between a single exercise, and the next more difficult, is often so slight, that the patient hardly appreciates that he is advancing. And above all when Frenkel has given a difficult exercise, that has in a measure tired the patient, he invariably follows with something much easier, that brings into play muscles that are sufficiently well educated to perform their function with ease.

Another important factor that enters into this treatment of these patients as a certain loss of tonicity of the muscles, which permits them to be stretched beyond their physiological capability. Frenkel has coined the word "hypotonia" to express this condition of the muscles. If a normal individual be placed upon his back, and an attempt be made to flex the extended leg upon the body, the leg can not be raised more than to form an angle of between 30° to 45° with the plane on which he is lying. But repeat this experiment with one whose muscles are hypotonic and the leg can be raised to an angle of 90° and in some cases can be brought over far enough to come in contact with the body itself.

The seriousness of this condition shows itself particularly in the knee joint. If the adjacent muscles are hypotonic, the knee joint is pressed back as far as the articular surfaces will allow, giving the familiar clinical picture of the retroflexed knee. It is for this reason also that Frenkel lays such stress on the inadvisability of exercises or apparatus that overtax the muscles, because they also stretch the hypotonic muscle beyond repair.

For several days after the arrival of the patient at Heiden he is allowed to rest, but during this time he is kept under observation, and is subjected to repeated careful physical examinations. According to the result of these examinations he is placed into one of several groups. Frenkel lays great stress upon the proper grouping, which is dependent upon the degree of ataxia and the condition of the muscles.

In order that we may better understand the grouping, I have arranged the following classification: (1) Those cases that show a mild degree of ataxia; (2) those that show a severe degree of ataxia; (3) those in which the ataxia has advanced so far that the patient is able neither to walk nor to stand without support.

Each of these large classes must be subdivided, for those cases that show no changes in the muscles, and those cases in which the muscles are markedly hypotonic, or in which some muscles or groups of muscles are paretic. As an illustration of this classification and the benefits observed in the reeducational treatment, I have selected six cases that may be considered to typify each of the three large groups and their two subdivisions. In giving a synopsis of these cases I shall omit the general anamnesis and symptomatology, and shall confine myself briefly to those points that bear particularly upon the ataxic gait.

Case I.—A man of 55 years of age in whom the diagnosis of locomotor ataxia had been made about 10 years previously. Under ordinary circumstances it was difficult to note any disturbance in gait, excepting when he tried to run. Then the movements of the legs became exaggerated, and the incoordination was very manifest. The muscles were well developed and there was practically no hypotonia. When this patient was first examined he had a marked Romberg sign, and was unable to walk if his eyes were closed or fixed upon the ceiling. He was, of course, placed in the advanced class.

After four weeks he was able to walk with little difficulty when his gaze was fixed on a point in the wall at a level with his eyes. After six weeks he was able to walk well while looking at the ceiling. About this time he had an attack of lancinating pains which prevented him from continuing his treatment for a week. When he again began his exercises he had retrograded to where he was after the fourth week, but within a few days he was back again to the point where he had been before the cessation of his treatment. At the end of two and a half months from the beginning of his treatment, he was able to walk the length of the hall, a distance of about 15 meters, with his eyes closed. Of course, in this last achievement there still was some staggering and the gait was ataxic, at the same time he was able to do that, which three months previously was impossible to him.

Case II.—This man belongs to this same group, but differs from the preceding case, inasmuch as his muscles were extremely hypotonic. He was 52 years of age and showed his first symptoms three years previously. His main complaint consisted in easily losing his balance when his attention was distracted, and also in tiring very rapidly. The examination showed a marked Romberg sign, and a high degree of incoordination when the eyes were not used to assist him in his movements. His gait, however, was mildly ataxic, and he was, of course, unable to walk with closed eyes. His muscles were remarkably well developed, and when stripped he presented the appearance of an athlete, which indeed he had been before the onset of his present condition. His muscles, however, were extremely hypotonic, so much so, that the thigh, when the leg was extended, could be flexed upon the body to an angle even greater than 90° and with extreme extension of the left leg itself, there was a marked pushing backward of the knee. This showed itself particularly when the patient walked.

This patient entered upon his treatment conscientiously and with great enthusiasm. In fact, he was too conscientious. Every movement in his exercises was accompanied by a tremendous display of muscular contractions, and each step was a feat of balancing, that it would have been difficult for one of good powers of coordination to duplicate. But at the end of ten weeks there was little or no improvement. It is true, he was able to use his legs better when they were relieved of the weight of his body, that is to say, he could coordinate better while lying down, but as far as his gait, or ability to walk unaided by his sight, was concerned, there was no improvement.

Case III.—A man 43 years of age, well built, and of good muscular development. Until a year before he was perfectly well, and had experienced no difficulty in walking. Being a man of methodical habits he had been examined from time to time, and up to the period referred to, no ataxic symptoms had shown themselves. A year ago he noticed that he was unsteady in his gait, and this particularly in the dark. The unsteadiness increased rapidly, so that he soon had to support himself with a cane, and walking became difficult. When he presented himself at Heiden the examination showed a classical case of tabes with marked ataxia of the lower extremities. He was unable to walk without the aid of his cane, and even then would topple over if his eyes were not constantly fixed upon his feet. His muscles were well developed and showed good power, although a slight degree of hypotonia was noted.

The man had been growing rapidly worse, and in a comparatively short time had lost his powers of coordination. Under these circumstances, inasmuch as there was probably still a progression of the process in the cord, it was not deemed wise to subject his muscles to any strain. Treatment was at first begun with the simplest exercises. After about three weeks there was practically no improvement in his gait, but it was at about this time that he began to be able to direct his legs better while in a dorsal position. At the end of six weeks he showed greater accuracy during his exercises in the gymnasium, and his bed exercises were marked by a much greater precision. After eight weeks he was able to walk firmly to and fro, the entire length of the gymnasium, taking measured step, and without support. At the end of three months he was able to do the same without looking at his feet, or in other words, with his eyes looking upward at an angle of about 45° to the ceiling. He has since then returned to his work and in his own words, "has continued to improve," "I am able, now," he writes me, "to walk with very little difficulty and find that I can get around comfortably in a dark room."

Case IV.—A man 62 years of age. He had been suffering from difficulty in walking for the past 20 years or more. This was not his first experience at Heiden, as he had already been under treatment the previous year. His symptoms were also classically those of locomotor ataxia. The Romberg sign was marked. His gait was very ataxic and he had great difficulty in walking without a cane. He was, however, not so dependent upon his eyes as one would be led to believe from the degree of ataxia that existed. Whether or not this was due to the treatment of the preceding year I cannot say. The muscles of the lower extremities were extremely hypotonic, so much so that there was a very marked pushing backward of the knees on extension of the legs. At

the end of the season there was little or no improvement. Objectively I may say there was no improvement, but the patient felt as if he was surer in walking and safer on his legs, and he seemed at times to show greater precision in his movements. So far as this case is concerned, however, I think that the betterment was really of phychic nature.

Finally we come to the last group of cases: those in which the incoordination had reached such a point that the patients were unable either to rise, stand or walk without material assistance.

Case V.—The first case of this group, or Case V, was in a man of 40, who, in the preceding year, was in such a good physical condition that he went on a hunting expedition, and within the year had made a successful Alpine ascent that required several days. The onset of his symptoms was severe and sudden, so that within two months he was bedridden.

When he first came to Heiden his condition was pitiable. Two persons were required to assist him from his bed to a chair, and he was practically helpless. All voluntary movements of the lower extremities were tremendously exaggerated, and he was unable to locate the position of either one of his legs unless he looked at them. What complicated this case, and made the condition still more difficult to handle, was the paralysis of the internal ocular muscles on both sides, so that the bulbi diverged and there was double vision. This was overcome, however, by placing a shield over one eye, so that by turning his head and bending forward, he was able to get a good view of his feet. He could not, however, see his knees very well, and this was a serious obstacle in his treatment. Notwithstanding the severe ataxic conditions, and the great loss of joint sensation as well as sense of posture, there was very little hypotonia. This was practically his condition on June 1. On June 15, while lying on his back, the movements of his legs had reached quite a considerable degree of precision. On June 22 he was able to stand momentarily without support. On June 29 he made two attempts to stand alone. In the first attempt he stood without any support for 1 min. and 45 sec., and then was allowed to rest. On the second attempt he stood for 2 min. and 20 sec., at the end of which, however, he lost his balance, and would have fallen if he had not been caught. The following day he was allowed to try to rise alone from a sitting posture in a chair. This he could not do, but with very slight assistance, viz., two fingers extended to him in order to steady him, he was able to attain the erect position by means of his own muscular strength, and then remained standing for 1½ minutes. At this time he seemed again to lose control of his right leg, and therefore was allowed to rest a few days.

On July 5 the exercises were resumed, and on July 8, for the first time he was able, unaided, to lift the left foot from the floor. The next day he made his first independent step. On July 12 he took seven successive steps without losing his balance. It was about this time that he was taught how to turn. This he learned very quickly, so that on July 20 he walked ten steps forward, turned, and retraced his steps.

These exercises had all up to this time been practised in his room, and as the space became too limited, he was wheeled every afternoon into the gymnasium. Here he progressed rapidly, and I need not enumerate the stages. By the middle of August he was able, unsupported, to rise from a chair and walk in measured steps a distance of about 12 meters. Before leaving this case I must say that the hypotonic condition of the muscles had increased somewhat, so that there was an indication of a slight retroflexion of the knee joint. This hampered the patient a little. But even then the hypotonia was mild.

Case VI.—This belongs to the second variety of the third group. This patient was 50 years of age and experienced no trouble in walking until a year previously. His first sensations were as if he was falling backwards. It was difficult for him to rise and seat himself, especially when the ground under him was not firm, as in a street car. From this time on he rapidly grew worse, until he was unable to walk, stand, or rise at all from a sitting position. The examination showed that, in addition to the regular symptoms of tabes, there was a paresis of the gluteal muscles, as well as the iliopsoas. In addition to Argyl-Robertson pupils, and absent reflexes of both the patellar and Achilles tendons, there was a marked incoordination of the lower extremities, which became very much exaggerated on closing the eyes. The muscles of both legs were well developed and of normal strength, but were extremely hypotonic. The weakness of the gluteal and iliopsoas muscles had, of course, much to do with the patient's inability to stand, and also gave him the sensation of falling backward. There was likewise a marked anesthesia of the skin over the buttocks, and this also hindered him from keeping his balance while seated. In addition to the above symptoms the sense of posture of the lower extremities was seriously impaired.

Throughout the treatment the weakness of the gluteal muscles acted as a serious handicap, but after the first three weeks the patient was able to get up from a sitting position, and stand unsupported for about two minutes. When, however, he tried to sit down again he fell backward. From this time on he began the most primitive forms of walking exercises but was allowed to steady himself with a cane. I mention this because he is the only patient at Heiden to whom Frenkel allowed the use of a cane during his exercises. The cane, of course, tended to give more support for the trunk, which in this patient was particularly wanting. A week later he was able to stand unsupported without looking at his feet, and was also able to walk with the aid of his cane alone, a distance of 3 meters.

It was about this time that the patient was seized with severe pains in his legs, and treatment had to be suspended for five days. When it was again resumed there was no apparent retrogression, and he continued slowly to get more control over his legs, so that after ten weeks from the time he first came to Heiden he was able to rise unsupported, and then, by the aid of his cane, walk with measured steps a distance of 7 meters, return to his chair, and seat himself. In the course of this walk he was also able to raise the cane from the ground and walk five steps without its use.

An examination of these six cases and the results obtained is interesting. What is most striking is that the three cases in which the muscles showed little or no hypotonia, the improvement of the ataxia was very marked. But in those cases where the tonicity of the muscles was very much impaired only one case showed any betterment. It is also noteworthy that in the four cases that did improve, the benefit derived was directly in proportion to the severity of the ataxia.

From my observations of these and the many other cases that I saw and cared for in Heiden, I have come to the conclusion that a majority of the tabetics can be materially helped by the reeducational treatment, that the greater the ataxia, the more benefit there is to be derived from this form of treatment, and that the prognosis is in a measure dependent upon the hypotonia of the muscles.

A PLEA FOR THE ESTABLISHMENT OF HOSPITALS FOR THE RATIONAL TREATMENT OF INEBRIATES.*

By CHARLES A. ROSENWASSER, M.D.,

NEWARK, N. J.

ATTENDING PHYSICIAN TO THE PRESBYTERIAN DISPENSARY; MEMBER OF ADJUNCT STAFF OF ST. JAMES HOSPITAL; VICE-PRESIDENT OF THE DEPENDENCY AND CRIME COMMISSION OF THE STATE OF NEW JERSEY.

In its report to the Hon. John Franklin Fort, Governor of New Jersey, the Dependency and Crime commission appointed by him for the purpose of making inquiry as to the causes of dependency and criminality and for the suggestion of remedial measures, says: "We desire to call attention to the importance of the establishment of a hospital for persons who are afflicted with the habitual addiction to alcohol and other narcotic drugs, so that they may be scientifically treated and restored to usefulness. It is the consensus of opinion that our present system of dealing with the inebriate who falls into the hands of the law, as he is very apt to do, is barbarous and inhuman, and is a relic of the Dark Ages. Punishment for drunkenness has been meted out for centuries, and has been proven to be an absolute failure. Why should this method be allowed to continue when there is a more rational method of dealing with these unfortunates, many of whom, through heredity and environment, are more sinned against than sinning? A method, which in the light of modern progress is as bright and full of hope as the present method is full of darkness and despair. The State needs most urgently a hospital for inebriates, as a means of preventing insanity, diseased and degenerate offspring, and dependency and crime. Aside from its incalculable value as a saver of men and women, it would be a great financial gain in the end."

That this statement is concurred in by practically every person who has given any thought to the question, you all know. You also know, however, that there are a large number of persons who are in absolute ignorance of the possibility, practicability and feasibility of restoring the inebriate to a life of usefulness, and that inebriety is one of the most curable of chronic diseases, provided, that treatment is begun in time, is properly conducted, and is persisted in for a sufficient length of time. It is plain, therefore, that in order to bring about the rational treatment of the inebriate, we must with renewed vigor and energy continue the campaign of education begun years ago by Turner, Rush, Mott, Crothers, Day, Parrish, Mason, and others.

Generally the public is skeptical as to the possibility of curing the alcohol or drug inebriate and hence we are asked: Can this disease be cured? Is it possible to restore the drunkard and drug user to a life of sobriety and usefulness? Let us consider the views of some of the world's most prominent students of the subject and acquaint ourselves with some interesting facts.

Dr. T. D. Crothers of Hartford, Conn., Editor of the *Journal of Inebriety*, author of many books and monographs upon the subject; a man who has devoted his entire life to the study and treatment of inebriates, says: "The best authorities unite in considering thirty-five per cent. of all patients remaining under treatment one year or more as permanently cured. . . . In view of the chronic character of these cases, these statistics are encouraging and indicate great possibilities for the future from better knowledge and treatment of these cases.

Dr. Day, for many years head of the Washingtonian Home, Boston, an institution now in the fifty-second year of its existence, made a study of eight thousand cases that had been under treatment and found over thirty per cent. sober and temperate. He says: "Twenty-two years of experience in this work has taught me that the task is neither hopeless nor thankless; nor would it be if the measure of success had been lessened one-half from the known rate of percentage of cures."

Dr. Mason, formerly of the Kings County Home, New York, examined the records of two thousand cases that had been away from the asylum for ten years, and found thirty-six per cent. of all cases cured. When we consider that in the above mentioned institutions the worst cases are encountered, the percentage of cures is encouragingly high.

That inebriety can be successfully treated and that a hospital for inebriates is a great saving and not an expense to the commonwealth, has been demonstrated to the satisfaction of the people of Massachusetts where, at Foxboro, there has been such an institution in successful operation for about eighteen years. From Mr. Robert A. Woods, president of the Board of Trustees, I learn that the average number of commitments last year was one hundred and twenty-seven, and a total number of four hundred and eighty men were cared for, most of whom were skilled workmen. The methods of this hospital include medical treatment in the first stage with stimulating industry, gymnasium and baths, proper diet, intellectual and moral stimulus, and visitation by volunteer visitors after discharge. An investigation is made each year as a result of which it is known that thirty to forty per cent. of the patients remain temperate for at least a long period, and from fifteen to twenty per cent. more show definite improvement.

Progressive Switzerland has long since learned that inebriety is a curable disease and that it pays to maintain a hospital for this purpose. At Ellikon, near Zurich, there has existed such a hospital for the past nineteen years. The result of its labors is most encouraging, and proves conclusively that the treatment of inebriety has long since passed the experimental stage. From its eighteenth annual report we learn that: Of five hundred and thirty-one patients discharged between 1889 and 1901 there were cured two hundred and forty, or forty-five and two-tenths per cent.; improved, one hundred and twenty-six, or twenty-three and seven-tenths per cent.; relapsed or unheard of, one hundred and sixty-five, or thirty-one per cent.

Of two hundred and fifty-five patients discharged between 1901 and 1906 there were cured, one hundred and forty-four, or fifty-six and four-tenths per cent.; improved, sixty-one, or twenty-three and

*Read before the American Society for the Study of Alcohol and Other Narcotic Drugs, at Washington, D. C., March 17, 1909.

nine-tenths per cent.; relapsed or unheard of, fifty, or nineteen and six-tenths per cent.

At Knoxville, Iowa, there has been in existence for the past three years a State hospital for inebriates, and the results thus far are very satisfactory. From the second biennial report of this institution we learn that of the entire number of patients treated (774), forty-one and one-third per cent. are known to be cured and living up to the conditions of their parole.

Minnesota has also taken the proper step in this matter and last year established a farm for inebriates. Surely the knowledge of the excellent results obtained in the above mentioned institutions, as well as the results obtained in the great number of private and public institutions for the care and treatment of inebriates in this country and abroad, ought to convince the most skeptical and should serve as a great stimulus in our efforts to overcome the obstacles which we encounter in the path of rational treatment of the inebriate, and there are many obstacles to be overcome.

Permit me to mention a few of those which I have encountered in my efforts to have a hospital for inebriates established by the State of New Jersey. History repeats itself, and, as there were editors of newspapers in days gone by who opposed the establishing of hospitals for the insane in Massachusetts on the ground that such institutions would foster the disease, and would attract patients from other States and even from foreign countries, there is to-day an editor of a Newark newspaper who opposes the establishment of a hospital for inebriates on practically the same grounds. I wonder whether he believes that the Church fosters sin.

My prohibitionist friends say that I am starting at the wrong end. They say "prohibit the sale of alcoholic beverages and there will be no more drunkards." But who believes that prohibition lessens the consumption of alcohol? What practical man doubts that the present so-called temperance wave sweeping over this country is aught but a manifestation of hysteria, and that it will soon begin to recede, leaving in its wake many a "wet" home which previously was "dry." Practical observers know that alcoholic beverages are now to be found in homes to which such beverages were strangers before, and there is good reason for believing that the percentage of children drinkers is growing. Our hope of true temperance lies in education, not in legislation. We know that inebriates have existed since the dawn of day. Who doubts that they will continue to exist until the crack of doom?

Some, who think themselves Christians, say: Inebriety is the result of the sin, and the sinner must and should suffer. Well, if this be true, let us close our hospitals and deny relief to every sufferer from whatever ill, for it may safely be said that almost all disease results from some violation of the laws of nature, and to violate the law of nature is a sin. This group of objectors is small but ever present. Its members are usually persons who are possessed of a high degree of selfishness. They can sometimes be brought to realize the importance of the rational treatment of the inebriate when informed that an habitual inebriate is as great, or a greater menace to society than an insane person, and every bit as much in need of restraint for the protection of the community.

The Binghamton Asylum Failure.—The failure of this, the first inebriate asylum to be established in the world, so far as is known, is a bugaboo which has been held up before me on several occasions. I am glad to have been able to look up the records of the Binghamton Asylum and feel sure that if ever failure was due to success, then the failure of this asylum is so to be charged. It appears that this institution was a private concern owned by a stock company. It certainly made money. There was a stockholders' scramble for the funds and for control and financial failure resulted. But so far as the curing of inebriates was concerned, this institution was a decided success, the results of treatment being most encouraging and satisfactory. I cannot imagine any greater loss to this country than was the failure of the Binghamton Asylum. Had it continued to exist, it would have served as an example to other states and countries, and similar institutions would have been established everywhere, and many thousands would have been saved from insanity, criminality, degeneracy, poverty, suffering and early death.

"Ostrich-like" objectors are also encountered. They prefer to hide their heads in the hour of trouble. They fear that the inebriate problem is too great to cope with. Needless to say no modern student of sociology flees from a problem on account of its vastness. He tackles it, because no problem can ever be solved in any other way.

The question of constitutionality has also been raised and it has been asked whether we can deprive a man of his liberty who is not insane, and who has not been convicted of a crime. Happily this question has been decided by the Supreme Court of Minnesota, which in deciding the case of Leavitt vs. City of Morris, says: "The State, in the exercise of its police power, has the undoubted right to punish drunkenness, and to provide for the detention and treatment in hospitals controlled by it of those who are habitual drunkards, and have so far lost the power of self-control that they are either incapable of properly caring for themselves or are a menace to the public weal. The State has the power to reclaim submerged lands which are a menace to the public health, and make them fruitful. Has it not, also, the power to reclaim submerged men, overthrown by strong drink, and help them to regain self control. . . . The State has for many years punished drunkenness by a fine or imprisonment. The trend, however, of legislation is to treat habitual drunkenness as a disease of mind and body, analogous to insanity, and to put in motion the power of the State, as the guardian of all its citizens, to save the inebriate, his family, and society from the dire consequences of his pernicious habit. . . . The hospital farm for inebriates is not a penal institution but a paternal one, seeking not the punishment of the inebriate, but the safeguarding of his interests and the safety of the public, by treating the inebriate as, what he is in fact, a man of unsound mind, and placing him under the guardianship of the State to the end that he may be healed of his infirmity."

Some say that a hospital for inebriates would merely be a place to which a man could go in order to sober up after a drunk. They are not aware that in institutions such as we are advocating patients cannot leave at will but are committed by law to be detained until they are cured or discharged or removed by law. Even though such a hospital would occasionally be imposed upon and in some way be

used as a sobering place, it would be hailed as a blessing by many wives and mothers who would be grateful for any relief, however small.

The question of expense is naturally an important one. It constitutes a real obstacle and one which is apt to frighten the legislators and the taxpayers. There is little cause for alarm, however, when we consider that many patients will gladly pay for their care, that the law requires pay from all who can pay, and that the indigents are now being taken care of at the expense of the City, County or State, in the general hospitals, jails, penitentiaries, workhouses, almshouses or insane asylums; and when we further consider that many of those who can be restored to usefulness are fast approaching the day when not only they but their families will have to be provided for by the taxpayers, the question of expense assumes a different hue. It is clear, therefore, that the State is not being called upon to bear any new burden, but simply to take up a burden which it is now carrying, in a more humane, hopeful, and enlightened manner. Who can estimate the ultimate gain to the State when we learn from conscientious students of the subject that at least 33 per cent. of insanity, 60 per cent. of epilepsy and idiocy, and 75 per cent. of arrests are due directly or indirectly to inebriety. Aside from the financial considerations, it is as much the duty of the State to control and scientifically treat the inebriate, as it is to restrain the criminal or madman, for in the prevention of crime and dependency lies our firmest security.

It should not be forgotten that hospitals for inebriates are also intended to take care of victims of drug habits, every one of whom is on the road to the insane asylum, and very many of whom can be absolutely cured if treatment is not delayed too long. For the drug fiend there is practically no hope unless he is scientifically treated under legal restraint, in a properly equipped hospital.

In addition to its value as a saver of men and women, a hospital for inebriates could also serve as a reformatory for women, for it is a well known fact that almost all fallen women are either alcoholics or drug users. It could remove the inebriate tramp from the streets and perhaps make him earn his bread by the sweat of his brow. It could serve as a center of learning for the medical profession with a field fertile with opportunity.

The people are awakening to the importance of the rational treatment of the inebriate, but the awakening is rather slow. They are busy fighting tuberculosis, and are making a gallant fight. So busily are they engaged in fighting the seed which produces the disease, that they are forgetting that no seed can grow unless it lodges in appropriate soil. Alcoholism prepares the soil and renders it fertile, and hence the fight against tuberculosis in order to be successful must at the same time be waged against alcoholism. I cannot here enter into a discussion of all the measures which have been and are advocated as preventives of tuberculosis and of alcoholism, but can say that all students of the subject agree that one of the most effective modes of warfare is by establishing in every state a hospital for the care and treatment of inebriates. There is good reason for believing that ere long there will be such a hospital in every State. Pennsylvania has already passed a bill to this effect, and the subject is receiving great attention in New York, New Jersey, and elsewhere. The movement has the support of the Medical Society of the State of New York, the Medical Society of New Jersey, the British Medical Association, numerous prominent judges, lawyers, ministers, and in fact of all persons engaged in humanitarian work, and of everything that is good and uplifting.

At present the Senate of New York has under consideration a bill introduced by Senator Grattan which provides for the establishment of labor colonies for the detention, reformation, and instruction of persons convicted of vagrancy and of habitual drunkenness. Under the provisions of this bill only those inebriates are accepted who have been arrested for drunkenness and sentenced to detention at the colony. There is no provision for the acceptance of patients before they have been convicted of drunkenness, not even if they desire to commit themselves voluntarily. This is a serious error and one which ought to be speedily corrected. As the bill permits the trustees to establish several colonies, it is to be hoped that they will see the wisdom of providing a place for those inebriates who are in the early stages of the disease, and for whom there is hope, before they provide for those who are in the last stages and in whom the possibility of cure is remote even under the best of care. And it is further to be hoped that some provision will be made for voluntary commitments, and also to enable a family to place their inebriate relative under control without being compelled to have him arrested and convicted of drunkenness. The same procedure might be followed in such cases as is now followed in committing the insane. Similar provision should be made for drug inebriates.

After studying the laws governing hospitals for inebriates in this and foreign countries, as well as the laws governing the commitment of insane in New Jersey, I drafted a bill for the establishment of a state hospital for inebriates and had it introduced during the present session of the legislature by the Hon. John F. Clark, Member of the Assembly from Essex County. In spite of the fact that the bill was ably championed by Mr. Clark, it met defeat, but only, I believe, on account of the condition of the State finances.

The bill (Assembly Bill No. 9) provided for commitments as follows:

A patient may commit himself by applying directly either to the superintendent of the institution or to the courts; patients who refuse to commit themselves can, provided they are inebriates as defined in the act, be committed on the certificates of two physicians, in the same manner as the insane are now committed in New Jersey; and, a committing magistrate may, at his discretion, commit to this institution persons convicted of minor offences, if the offense be due to alcohol or drug using.

In an article entitled "The Drink Habit and Its Treatment," which I read before the Medical Society of New Jersey, I called attention to the fact that the drink habit can be cured in a gratifyingly increasing number of cases without requiring the detention of the patient, provided the treatment is begun in the early stages of the disease. In view of my convictions, I have provided in the bill that the superintendent of the hospital may, at his discretion, treat without detention persons who voluntarily apply for such treatment, if, in his judgment, they are suitable patients for such treatment. I have done this in order to make it possible to reach that large number of patients who are in the early

stage of the disease, who will not voluntarily place themselves under restraint, and who cannot be committed by the courts because they have not advanced to the stage where they can be included among those persons who are termed inebriates within the meaning of the act.

The bill says: The term inebriate, as used in this act, includes every species of inebriety, and extends to every person who is suffering from inebriety, whether caused by the periodical or habitual excessive use of intoxicating liquors, morphine, opium, cocaine, chloral, or other narcotics, and who, as a result of such excessive use of intoxicating liquors or narcotic drugs, has become incapable of controlling himself or his estate, or is wasting his estate, or is a menace to the public weal.

All patients are committed to be detained until they are cured, or discharged, or removed by law. No person can be detained longer than two years without being permitted to leave on parole.

At the present time there is in New Jersey only one way in which an inebriate who is a menace to himself, to his family and to society, can be placed under legal restraint if he is not convicted of crime or is not insane, and that is under the provisions of the Habitual Drunkards Act. Under this act an habitual drunkard can be committed to an insane asylum, but Chancery proceedings are required, and the cost is several hundred dollars. This act is therefore available only to those possessed of worldly goods. To send to an insane asylum an inebriate who is sane is, moreover, a great error.

Left to himself the inebriate is practically helpless and hopeless. The disease is progressive, and gets worse as time goes on. Under proper treatment the outlook is as hopeful as it is in almost any other chronic disease. Insanity has yielded marvelously to scientific treatment, and we are more than justified in the light of modern progress to expect likewise marvelous results from the rational treatment of the inebriate. Hence this plea.

214 South Sixth Street.

EXAMINATION OF THE LUNGS BY ROENTGEN RAYS.*

By HENRY HULST, A.M., M.D.,
GRAND RAPIDS, MICHIGAN.

A short time ago a medical colleague undertook to ascertain the consensus of opinion of the leading internists and phthisiotherapists in this country on the value of the Roentgen rays in the examination of the lungs. I cannot enter into an analysis of the answers received. Suffice it to say that they were not very enthusiastic and did not differ materially in general tenor and import from the average expressions on the subject met with in textbooks and current literature.

Speaking of lung examination, Hildebrand asserts: "The Roentgen rays have added nothing in certainty to the older methods." Butler says: "The very considerable expense of the necessary apparatus, the technical skill required in its management, and the personal training and experience which are required before trustworthy work can be done, places *x*-ray diagnosis for the present in the hand of the expert." Lawrason Brown sums up by saying: "The *x*-ray examination can hardly be said to repay the study necessary to acquire all the details and should be relegated to the *x*-ray expert."

*Read before the Ninth Annual Congress of the American Roentgen Ray Society, held in New York, December 28, 29, 30, 1908.

According to my opinion there are a number of sufficient reasons to account for this attitude on the part of the medical profession, some of which were valid at one time but none of which is insuperable.

For instance, lung pictures are quite unsuitable for publication by ordinary medical journal methods, and those published in spite of this have served only to discredit roentgenology. Until publishers take as much pains to do justice to roentgenographs as does for instance the *Fortschritte auf d. Geb. d. Roentgenstrahlen,* we should refuse to permit them to print anything beyond pictures of broken bones.

Secondly: In the first excitement incident to the discovery of these wonderful rays, the profession was stimulated to expect altogether too much from the rays in general and from fluoroscopy of the lungs in particular. The natural reaction followed. Especially fluoroscopy, which was at first applied indiscriminately, soon lost its popularity.

I am not one to decry the fluoroscope as an invention of the devil because some were burned by it. Even though lessened excursion of the diaphragm on the affected side, Williams' sign, which was discovered by the fluoroscope and is best studied by means of it, has not the diagnostic significance assigned to it by some, we have nothing yet, after all, to equal it for the study of the phenomena of motion; and for this I have always used and appreciated it.

Even ordinary fluoroscopy, moreover, enables us to see coarse, dense lung lesions better than their existence can be inferred by the most refined percussion through the sense of hearing. But the fine detail to which we have grown accustomed in the case of hard tissue roentgenography, and which is just as essential in the case of soft tissues, the screen fails utterly to reveal. So long, therefore, as general diagnosticians and expert phthisiotherapists confine their roentgenological endeavors to fluoroscopy and the occasional production of a negative of the chest by some hireling or willing nurse, these leaders of medical thought and opinion will continue to write about the rays as they did to my medical friend, and the profession will continue to doubt and do nothing. I am aware that some sanatoriums for the study and cure of tuberculosis make use of the rays. Also a better class general hospital here and there under the sphere of influence of some individual enthusiast makes *x*-ray examinations of the chest. But what have they done for the roentgenology of the lungs? Medical roentgenology must be developed by medical men, not by photographers. The expert internist even though he relegate urine, feces, sputum, and blood examinations to assistants, cannot afford to sit by while the druggist's clerk does the percussing and auscultating. Either the surgeon must roll up his sleeves and use his own hands, or the barber must develop into surgeon. Not until internal medicine has succeeded in benevolently assimilating the rays, and has formulated the principles underlying and described the rules governing medical roentgentology, as surgery has done for itself, will it honestly earn the right to relegate Roentgen-ray examinations of the lungs to the expert, whose existence it gratuitously assumes, or to express any opinion on the subject whatsoever. Then, but not till then, is internal medicine or phthisiotherapy entitled to follow the example of surgery and employ a medical roentgenological expert as the Mayos do Dr. Willey.

The density differences of lung structure, even when expanded by air, are much less than between muscle and bone, and their reproduction on the photographic plate is proportionately less easy. This inherent difficulty constitutes a third and more valid reason for the comparative backwardness of the roentgenography of the lungs and lack of interest in it on the part of the profession. To overcome it has constituted the dream of every roentgenologist. The slowness with which this dream is being realized may seem paradoxical without some explanation.

To obtain a structure picture of the bones of the body we may within certain limits compensate for increased softness of tube by using a stronger current or making a longer exposure, or both. It is moreover not easy to lose a bone by too long an exposure or too strong a current, if only the rays be not too penetrating, that is, if only the tube remains soft enough. Indeed, but for the risk of burning the patient, even softer tubes might be profitably employed in bone work than are ever thought of now. But as soft rays reduce more silver on the photographic plate than those relatively more penetrating, long before the bones are done, the soft tissues will have been rayed into utter darkness. In fact the softer the tube and the stronger the current or the longer the exposure, the greater will be the damage done to the soft tissue part of the picture. This procedure, though ideal for what it was at first intended—hard tissue work—when applied indiscriminately on all occasions and for all purposes within the limit of safety to the patient, reveals a bad habit. Holzknecht's recent prophecy—"Not by shortening the time of exposure, but by selecting less penetrating rays and stronger currents the roentgenography of the future will secure its better result," instead of being a "primum verum" is a "proton pseudos," a one-horse method, whose slavish adoption must be overcome.

Formerly chest pictures were made in this manner. Through the mistaken endeavor to produce what was taken to be, but really was not, a beautiful negative, the ribs, vertebræ, and heart were made to stand out boldly as clear glass against a background of the blackest possible of lung. Such a picture is brilliant because the lungs are pitch black; it is emphatic because it has no meaning. Contrast and emphasis, though more striking than detail and meaning, in roentgenography as well as in other modes of expression and reproduction, represent the earlier stage of their evolution. The first period of roentgenography, the period of screaming contrasts, must pass over into that of detail in contrast. Roentgenography of hard tissues must lead to that of the lungs as well. The first to show the way was Dr. Rosenthal, of Munich, in 1899. The first to get out of the old rut of making long exposures and to produce genuine lung pictures were Prof. H. Rieder and Prof. H. H. Ziemssen in their epoch-making atlas: "Die Röntgographie in der inneren Medizin," in 1901. These were the result of one-second exposures, but with the aid of two intensifying screens to reinforce the rays. The first pictures of the lungs made in America by one-second and shorter exposures, but without the aid of intensifying screens, were exhibited by myself at the meeting of the American Roentgen Ray Society in Chicago in 1902.

This most important revolution in technique created the new roentgenography of the lungs and was accomplished not, as of late some would lead us to believe, as a result of improved apparatus, but through acquired skill in managing the apparatus already at our disposal, according to the principles described. For a long time my one-second and shorter lung pictures were made with a coil of 18-inch spark length designed to be worked with an old-fashioned hammer break, but adjusted to run on a home-made Wehnelt interrupter. Not that such an instrument is satisfactory; but neither are the finest coils and rectified transformers. Any instrument to be ideal must maintain a constant uniformly sustained potential difference at the terminals of the tube as well as furnish a current of adequate strength. Coils and transformers fail to meet the former requirements. Instead of supplying a constant flow of current through the tube, they violently force through it a series of electrical discharges, whose individual amperage drops from a high maximum to zero. The inevitable result is abuse of the tube and a quantity of heterogenous rays, many of which are harmful because not wanted.

Static electricity, as is well known, is entirely free from these defects. It produces more definite homogeneous rays and satisfies the ideal requirements in every respect. Just one thing has prevented its adoption for heavy Roentgen-ray work, the difficulty of getting enough of it.

The Toepfler-Holtz machine projected on the screen stands for the result of the latest effort to overcome this difficulty. This high tension generator, as he loved to call it, was the last and crowning achievement of our colleague, who met with us for the last time a year ago in Cincinnati, the late Dr. Richard V. Wagner of Chicago. It is not unlike an ordinary static machine laid on its back. That is, the 50 mica plates of 70 cm. diameter are rotated by a vertical shaft. The 50 glass stationaries are split through the center. A 5-h.p. motor, coupled directly to the shaft, is on top of the strongly built hexagonal cabinet and is capable of 1,800 r.p.m.

The full discharge from a positive point to a negative disc, 4 inches in diameter, measures about 40 cm. in length and is a deafening torrent of bluish white sparks; passed in opposite direction, the sound rises in pitch until a silent flame curls with a sweep backward, then upward from positive disc to negative point.

This flame, unlike any other probably ever seen from a static, is both thick and yellow. Twelve milliampères of this current through a Walter 6 tube enabled me to take a picture of a kidney stone in a large woman in two seconds. A sharply focussed Müller ran 30 seconds under identical conditions without the target being affected in the least. To quote myself: "The extremely short exposures which suffice for work requiring the maximum current and the perfect ease with which a fine delicate tube transforms such a current into rays of uniform penetration, prove, all other things being equal, the vast superiority of a really adequate static current over all others hitherto employed."

The value of the rays in the diagnosis of thoracic diseases constituting the more material aspect of my subject was assigned a separate number on the scientific program of this congress and does not therefore call for a detailed discussion here. However, the former points to the latter, and is incomplete without it. The rays reveal the lungs; this revelation should be authentic, genuine, and as complete as possible, but also needs to be interpreted. The fact that some roentgenologists speak of counting the number of individual fresh tubercles present

in a lung, while Rieder thinks that fresh tubercles connot be seen at all, and that their shadows are at least composite or superimposed, may serve to show the necessity of a sound exegesis instead of a systematic dogmatism on the strength of a disputed text.

This requires practical familiarity with the symptoms and signs of physical diagnosis, but especially with anatomico-pathological changes. The data furnished by auscultation and percussion are less direct, as well as less accurate, more inferential and less specific than those obtainable by fluoroscopy and roentgenography. It is to the comparison of the half-tones and shadows of the negative with the actual lesions themselves that we look for an adequate reading of all this hieroglyphic wealth of detail. A good deal is already familiar, strings of minute beadlike structures often no larger than a pinhead following the ramifications of vessels and bronchi; isolated and massed bronchial and pulmonary glands; merely enlarged or caseous, sarcomatous and soft, as well as calcified and hard, areas of consolidation; effusions; thickened pleuræ; and cavities both deep and small.

In this connection I may mention that about a year ago I first noticed in an uncommonly good lung picture a spot which I could not interpret and which I was astonished to find afterward more or less clearly defined in every normal lung negative. It appears as a relatively dark area, about the size of a dollar, not far from the right hilum, and corresponds to the space between the eparterial bronchus and vessels to the upper and the hyparterial structures to the middle lobe of the right lung. It has not been possible to locate it by percussion.

An interesting problem remains for pathology to solve. Roentgenologists have learned long ago to look to the hilum instead of the region supplied by the posterior branch of the eparterial bronchus for the earliest evidence of tuberculous invasion. Negatives revealing apical involvement show hilum alteration as well. On the other hand, when the lungs themselves appear normal, enlarged and even calcified glands are often seen about the hilum. The shadows due to the vessels and bronchi crossing each other, often quite marked in mitral insufficiency, should cause no confusion.

Dissections have proved the well-defined dense spots so frequently seen in so-called normal lung pictures to be calcified glands. These are records of past conflicts and partial or complete victories over disease, and are so common that it is difficult to find adults without them. Thus "normal" applied to the lungs as well as to the position of the stomach seems to be the exception. Naegeli, I believe, demonstrated evidence of tuberculosis in 98 per cent. of postmortems in a total series of 500.

The diagnostician who neglects the Roentgen rays in his examinations of the lungs has no conception of the rich field he is neglecting. But a rapid change in this respect is working its way. Last April an entire Congress was devoted to this single subject in Berlin. Prof. Wenkebach, of the University of Groningen, Holland, makes stereoscopic pictures of every chest examined and his students are trained to consider no examination of the lungs complete without this.

The time is coming, and we should hasten it, when this will be done in our country as well. To this end chairs of roentgenology, not footstools, must be established in Johns Hopkins, Cornell, Harvard, The University of Michigan, and other great universities, and efficient Roentgen ray laboratories in connection with all hospitals and sanatoriums for the study and treatment of diseases of the lungs.

THE RELATION BETWEEN ANEURYSM OF THE AORTA AND TABES DORSALIS; WITH THE REPORT OF A CASE.*

By PAUL H. BIKLÉ, M.D.,

PHILADELPHIA, PA.

Lesser[1] has recently called attention to the fact that in approximately twenty per cent. of the cases of tabes dorsalis which he has observed, he has found aneurysm of the aorta. This not infrequent occurrence of the two conditions has suggested the question whether, in lieu of the unquestionably frequent dependence of each on syphilis as a causative agent, there may not be in tabes itself a peculiar toxine or condition which exerts an influence on the arterial walls, affecting them in some way which renders them less able than normally to withstand intra-arterial pressure; or whether the intraarterial pressure which, according to Heitz and Norero[2], is determined by gastric crises, and particularly by the lightning pains, may be a factor in the production of aneurysms. In other words, is the occurrence of the two affections in the same patient merely a coincidence, or shall we find in such cases tabes itself, or a toxin peculiar to the two conditions to be the underlying cause of the aneurysm? Lesser suggests the possibility of such a dependence.

Arterial disease is manifested chiefly either in a generalized fibrosis of the vessel walls or in a localized circumscribed nodular form, characterized by the development of scattered patches of atheroma and calcification of the arterial coats. In both instances the elasticity of the vessel wall suffers, but in the nodular form there is less expansibility than in the other, where there is simply a fibrosis. It naturally follows that the less expansile the vessel, the more prone it is to rupture when intraarterial pressure is increased, while under the same conditions, if the pressure is great enough to cause any damage, the more expansile form will more probably permanently dilate than rupture. This fibrous form is, according to Flatau, Jacobsohn, Minor,[3] and others, the variety of arteriosclerosis caused by syphilis, while the nodular sort, associated with calcareous deposit, is due to old age, chronic alcoholism, and plumbism, prolonged physical exertion, exposure, and other similar conditions.

There can be no doubt that syphilis is one of the most frequent causes of aneurysms of the aorta, but wide differences exist in the opinions of writers concerning the degree of the frequency of its relation to this form of vascular disease. The extremes are represented on the one hand, by M. Schmidt, who finds syphilis present in 29 per cent. of cases, and on the other, by Drummond, who believes that lues is responsible for aortic aneurysms in every instance. Debove[4] also shares the latter view, while Gerhardt, more conservatively, regards 53 per cent. as nearer the truth.[5] Julius Citron,[6] in a recent consideration of the relationship of syphilis to aortic insufficiency, calls attention incidentally to the frequency of lues as a cause of arteriosclerosis.

*From the Laboratory of Neuropathology, University of Pennsylvania. Read before the Philadelphia Neurological Society, February 27, 1909

and this same idea permeates all the literature on the subject.

The Wassermann test has been employed by Albert Schütze[7] in cases of aortic aneurysm, only to prove again the existence of a previous luetic infection in almost every case. Confidence in this test is growing rapidly, and it is another instance of a clinical method of precision confirming an opinion which had previously existed for years.

The presence of aneurysm may, at times, establish a syphilitic infection as a certainty. Nonne[8] has recently expressed the belief that reflex pupillary rigidity and failure of pupillary reaction to light and convergence as the only signs of disease are not conclusive of syphilis, since they may be produced by uncomplicated chronic alcoholism. Isolated organic pupillary anomalies with some disease of the aorta, such as aneurysm, however, have in his experience shown themselves only in cases with a syphilitic history, and he shares Strümpell's view that this symptom-complex must be regarded as indicative of syphilis. In the same paper he takes occasion to emphasize the suggestion that the variation in the intensity of the symptoms of diseases of the nervous system caused by syphilis is decidedly less than is usually thought .

Syphilis is likewise, without question, the chief etiological factor of almost all the cases of tabes. Fournier, in 1875, first called attention to the parasyphilitic nature of the disease. He has reported 87 to 93 per cent. of cases as due to syphilitic infection, while Déjerine found 92 to 94 per cent., and Church, out of a series of one hundred cases, found only two which failed to disclose a history of syphilis[9]. W. Erb[10] thinks it probable, though not absolutely proven, that all cases of locomotor ataxia are due to syphilis. Schütze[7] has employed the Wassermann test in cases of tabes also, and has demonstrated the almost constant luetic history in cases of the disease.

In the instances where tabes and abdominal aneurysm are found associated, it is natural to question whether the pains that are experienced may not be partially due to the pressure of the aneurysm on certain nerves. Such a dilation of the aorta, if of sufficient size, may cause pains which are lancinating in character and very similar to those of tabes, particularly if such dilation is located low enough to press upon the lumbar nerves. When high in the abdomen, it impinges upon the solar plexus and splanchnic nerves, causing a more fixed and constant pain in the back. Thus, in a given case, where tabes is known to be present, it is obvious that this symptom of an aortic aneurysm in the abdomen may readily be attributed to the tabetic condition. It is possible, indeed, that such was true in the patient described below. The masking of tabetic pains by the pains of an aortic aneurysm known to exist in the abdomen, could, it seems, just as easily occur.

When we remember, then, that syphilis is an important cause of both aortic aneurysm and tabes dorsalis, and when it is observed that they frequently occur together, the question suggested by Lesser not inaptly arises whether there may be in tabes dorsalis an etiological factor in the production of aneurysms of the aorta. We are inclined to believe that this association which, as has been shown, not infrequently exists, is merely accidental, and that each, in such cases, is a parasyphilitic condition independent of the other. Gowers[11] considers that valvular heart disease complicating tabes is merely a coincidence of causes—both being of syphilitic origin—and the importance of this view in supporting the contention that the same relation exists between aneurysms and tabes is apparent. The researches of Heitz and Norero[5], briefly referred to above, in which they made a study of eight cases of tabes with more or less ataxia, in order to determine the modifications in the arterial pressure under the influence of gastric crises and lightning pains, do not militate against this view. It is true that during the crises there is usually a vasoconstricting spasm, except in advanced cases in which the reflex phenomena are less active. The peripheral lightning pains were found to determine hypertension, and the inhalation of amyl nitrite is usually followed by the relief of pain at once—both abdominal and peripheral—and this relief, as a rule, proves permanent even after the blood pressure has returned to its normal level. Röhmer[12] has recently attempted to demonstrate that subcutaneous injections of suprarenal extract have a curative effect on the pains of tabes. This, if true, is obviously contradictory to the results of Heitz and Norero, which showed the palliative effect of a vasodilator on the same condition. Notwithstanding these facts and that the pulse was found to be accelerated during gastric crises, the experiences related seem to show that the cardiovascular system does not suffer from the repetition of the tabetic pains as much as one might suppose, and while the increase in intraarterial pressure and pulse rate associated with them might be regarded as a factor favoring the production of aneurysm, yet these changes are not sufficiently marked to carry with them any appreciable weight in the production of these aortic conditions. Moreover, we cannot lose sight of the cases of aortic aneurysm which occur in patients with a history of syphilis where tabes never developed; nor, on the other hand, of the many instances of tabes of syphilitic origin which, while the usual amount of arteriofibrosis may occur, yet there is not the formation of aneurysm. Whether the toxine is unique or more virulent, or the resistance of the patient less, in the cases where the two conditions are associated, must, to a certain extent, for the present at least, remain a mooted question, but we believe the better view supports the opinion of Debove[4] that the coexistence of the two conditions is only a coincidence and entirely independent of the virulency of the toxine, the resistance of the patient or any other factor.

For the privilege of reporting the following case, I am indebted to Dr. Spiller, the patient having been in his service in the Philadelphia Hospital:

J. P., age 39, admitted January 28, 1908, complaining of nausea, vomiting, incontinence of urine and feces, pains in the lower limbs, and loss of power in the left lower limb. His family history was negative. His occupation was that of a huckster. He was a widower with no children and his wife had had one miscarriage. He had gonorrhea several times and a hard chancre at the age of seventeen. He used alcohol in large quantities and indulged in great sexual excesses. With the exception of the present trouble he was never seriously ill.

The present illness began seven years ago with loss of control of the bladder and rectum, and with shooting pains in the legs. The power of walking gradually became worse so that his gait was very ataxic. The shooting pains became intense. The week previous to his admission he was not able to

move his left lower limb. He had considerable vertigo and also cough and expectoration.

Examination: Pupils irregularly oval, right reacting feebly to light and the left not at all. Both reacted well to accommodation and convergence. No ocular palsies, ptosis or nystagmus. Upper limbs showed marked ataxia. Grasp equal on both sides. Biceps and triceps tendon reflexes absent. Lower limbs markedly edematous, and showed some muscular atrophy. Power to move left decidedly less than right. There was resistance to passive movement on each side. Heel to knee test showed marked incoördination on both sides. Patellar and Achilles tendon reflexes absent on both sides. No plantar reflex or ankle clonus. There was inability to walk or stand. Sensation impaired over entire body—practically absent in lower limbs. Sense of position was greatly lessened. Mentality was good and speech was normal.

Eye examination showed vision to be 4/5 in each eye. Media clear, discs pale only in papillomacular bundle. Vessels normal in size.

He gradually grew weaker, the cardiac condition increased in severity, and he finally died on March 14, 1908.

The autopsy findings were, in addition to chronic tuberculosis of both pulmonary apices, chronic fibrous endocarditis of mitral and aortic valves, tuberculous ulceration of small intestine, chronic parenchymatous nephritis, a large retroperitoneal mass which was found to be a false aneurysm. Beginning at the diaphragm, the aorta widened out into an irregular sac which was connected with the lumen of the aorta by an opening 4 cm. in diameter. The edges of the opening and adjacent tissue were made up of tissue similar to that of the aortic intima. The bodies of the last dorsal and first lumbar vertebræ were much eroded. Over the lower vertebræ lay a firm, yellowish-white membrane. At the margins of that portion of the sac whose walls resembled the intima of the aorta, and whose boundaries were difficult to determine, began a white stratified clot which lined the false aneurysm. Inside of this was a currant-jelly clot. The original sac measured 12 cm. in diameter while the false sac extended on either side from the diaphragm to the iliac region.

Gross examination of the cord showed a diminution in its size with a thickened and slightly opaque pia. The posterior columns were visible as a gray band throughout the whole length of the cord. On section, the contraction of the posterior columns was conspicuous, and a gray translucent appearance was evident. The posterior nerve roots shared in the atrophic process, and were small and gray. Minute examination showed intense degeneration and sclerosis of the posterior columns and roots with marked round-cell infiltration of the pia.

With the exception of a somewhat thickened pia, infiltrated with round cells, there was nothing abnormal found in the brain.

ECZEMA.*

By SAMUEL STERN, M.D.,

NEW YORK.

RADIOTHERAPIST TO MT. SINAI HOSPITAL (DR. LUSTGARTEN'S CLINIC).

The name eczema often covers a number of dermatological sins. Almost every form of skin disease for which a proper diagnosis has not been found is usually catalogued as such. A friend of mine, who is chief of a dermatological clinic, on his return from his vacation found that almost two-thirds of all the new cases that had presented themselves during his absence were diagnosed as eczema by his assistants. There is no doubt that the disease makes up a large portion of skin diseases, but, of course, the percentage is nothing like this.

The term is used to describe a form of skin disease which begins with an erythema followed by vesiculation, the formation of papules and pustules, accompanied by serous exudation and finally running into desquamation. The different names of erythematous, vesicular, papular, pustular, or squamous eczema are merely used to denote the stage of the disease or the most characteristic predominating symptom. The special forms of eczema are seborrheic eczema when the affection begins in the sebaceous glands, sweat-eczema when it begins in the sweat glands, eczema folliculorum when it begins in the follicles, and nervous eczema when it is the result of reflex irritation.

There is a type known as artificial eczema, which is produced by various forms of external irritants, but this, while it shows all the symptoms of eczema, should really be considered as a form of dermatitis, as it generally yields as soon as the cause of irritation is removed.

The general symptoms of eczema are itching, burning, and pain. The main symptom is the intense itching, which may be so bad as to become almost intolerable, and this symptom can generally be relied upon as one of the main diagnostic symptoms. If a patient gives you a history of an eruption with an intense itching, and you can exclude prurigo, mycosis fungoides, dermatitis herpetiformis, scabies, and the different forms of lichen, you are almost safe in regarding it as a probable eczema—especially if you see the most characteristic objective symptom, namely, the "weeping" of the lesions. I do not mean to infer that these are the only skin eruptions accompanied by itching, but they are the conditions most frequently mistaken for eczema. Sometimes the complications produced by scratching and the infections produced by various pus cocci make the diagnosis a little difficult, but as a rule it does not present much difficulty.

As to the etiology of eczema, we know nothing definite as yet. There is no question that predisposition is a very important factor. The condition is practically that of a catarrh of the skin, and just the same as a lot of individuals are predisposed to the development of catarrh of the mucous membrane, a large number are predisposed to the development of catarrh of the skin. This predis-

*Read at a meeting of the Richmond County Medical Society, December, 1908.

position and the various forms of irritation I mentioned seem to make up the strongest etiological factors. Just how important a rôle microorganisms play in its development is difficult to determine. Some authorities claim that practically every case of eczema is due to microorganisms, others claim that microorganisms simply make up a secondary factor. Several very careful observers have shown that the contents of the vesicles for a few days after their development are absolutely sterile. There is a form of eczema which is unquestionably parasitic from its beginning; in appearance the pustules are predominating, and they appear most often on the hands and feet, occasionally on the face. To differentiate this form we have termed it parasitic eczema.

The general parasitic theory of eczema is gradually gaining a stronger foothold among dermatologists, and I think it is only a question of time when the specific microorganism will will be proven conclusively.

Treatment.—I am sorry to be compelled to say that a large number of general practitioners seem to know very little about the treatment of eczema. It is an every-day occurrence to us to see patients in our office who have been treated for years by general practitioners with the condition continually growing worse. Four weeks ago I saw a girl of 15 in my office who for the past 2½ years had both her hands completely bandaged for a parasitic eczema which has been continually progressing. She was constantly under treatment by various physicians, who practically regarded the case as hopeless by this time. To-day, after four weeks of treatment her hands are entirely clear, and there are practically no remaining evidences of the disease. She told me that the physicians she went to gave her all sorts of internal remedies, advised her to soak her hands in warm water twice a day, and apply various ointments which they prescribed. It is no wonder that under this treatment her hands got continually worse. I am sure that if this had been kept up for eternity her hands would not have improved. This is not an isolated case, but a history we very often have to listen to.

There is no question that with our advances in dermatology we can cure eczema to-day, even of the worst types. The duration of treatment necessary in a medium severe case is about from four to six weeks. Of course, there might be recurrences, but you must not forget that you are dealing with a catarrh of the skin, with a patient who is predisposed to the development of this catarrh, and who, under the stimulus of the various irritating causes mentioned, may develop the disease again.

This holds good to about the same degree as a recurrence of a catarrhal inflammation of the mucous membrane will hold good. The internal treatment is of some importance in the treatment of eczema. It is important to get your patient in as general a good condition as you possibly can, especially when the disease is due to nervous reflex irritation. You must take care of the patient's nervous system; you must correct any faulty digestion and imperfect elimination. You must take care of the circulation. The theory of arsenic being a specific in eczema has not been proven, and it should be abandoned as a routine treatment; an all around intelligent symptomatic treatment is far better.

As regards diet, I do not know of any special diet which is of much use in treating eczema. In the parasitic form, diet does not influence the disease in any way whatever. In other forms, any rational simple diet will do. Probably cutting out alcoholic stimulants will prove of some benefit. Occasionally you will get a patient who will tell you that eating various substances, such as shell fish, etc., makes his eczema much worse—probably it does through the reflex nervous system—tell him to abstain from it; but these are all individual cases. It may be necessary to make radical changes in the diet of some patients who are subject to various ailments which more or less influence his eczema, such as a gouty diathesis, rheumatism, excess of uric acid, diabetes, etc. In these cases you must treat these conditions in addition to the eczema.

External Treatment.—In the majority of cases this is far more important than the internal treatment. In my opinion the most important thing is to avoid absolutely the external use of water in any shape or form. Never permit water to touch an eczematous lesion. It is the worst form of irritant that you can apply. For cleansing purposes, use cold cream or some neutral oil. If there are a lot of exudations or crusts on the lesions, you can best clear them off by gently rubbing in some fatty or oily substance and wiping off with absorbent cotton. If the lesion is erythematous, or in fact in almost all types of eczema, we had very good results at the Mt. Sinai Hospital in first applying the following solution, known as "Liquor Burrowii":

Plumbi acetatis cryst, ʒii
Alumini crudi pulv. ʒiv
Aquæ dest. ʒviii
Dissolve separately, mix, and filter.

This is best applied by diluting it with 4 parts of water. You order a thick piece of sterilized gauze saturated with this solution applied on the lesion covered with a piece of oil-silk and tied on. Be sure that the oil-silk somewhat overlaps the gauze, otherwise it would dry too rapidly. This should be renewed whenever dry, probably every 3 or 4 hours. You will find that it has a very soothing action on the lesion, that it will generally allay the inflammation, and that after using it for a time the vesicles and pustules will begin to show a clean base. After all the inflammation has disappeared, you follow up with a tar preparation of some form. The one we have found best is the imported oleum rusci with a zinc oxide ointment base. It is perhaps best to begin with a 5 per cent. preparation and increase up to 10 per cent. The best way to apply this is to clean the lesion morning and evening with oil or cold cream, then gently apply ointment, dust over with plain, nonscented talcum powder, and lightly bandage. In cases of dry scaly forms of eczema of the seborrheic type, situated on the scalp or other portions of the body, apply the oleum rusci mixed with olive oil in the proportion of 1 to 3, painting it on twice a day with a skin brush.

In the form of eczema generally found on the palms of the hands and feet (large bleeding cracks, generally known as washerwoman's eczema), we get the best results by painting every day or two with a 5 per cent. solution of silver nitrate, and then applying a 5 to 10 per cent. salicylated plaster. The best is the imported plaster known as: "Emplast. Sapon. Salicyl. (Dieterich)."

Another type of eczema we often find in children, beginning on the back of the scalp, spreading down to the neck, involving the ears, with isolated patches scattered over the face, really belongs more to the impetigenous conditions than to eczema. These

can generally be traced back to pediculi. We must treat this condition before we can expect to accomplish anything with the eczema.

Another drug which I have found very beneficial in a great many cases of eczema is methylene blue. This can be painted on the lesion in a 3 per cent. aqueous solution, or applied in the form of a 3 per cent. ointment with zinc oxide ointment base. Small isolated patches which are not much inflamed can be painted with the methylene blue solution and then painted over with flexible collodion—this makes a very good dressing.

The most important adjunct we have in the treatment of eczema is the *x*-ray. It is often marvellous to see the way old chronic eczematous conditions will yield to the *x*-ray. I have repeatedly seen cases that resisted every other form of treatment cured by these applications. There is a certain amount of fear in the lay mind connected with the *x*-ray. There is no question that a great deal of harm can be done with the ray, but no more than can be done with the improper administration of morphine or any other poison. Carefully administered, there is rarely any reason why it should have any bad consequences. Within the last five years, I have given probably 20,000 *x*-ray exposures without a single serious mishap. It is not surprising that a large number of patients have a certain amount of fear of the *x*-ray. Not only the lay press, but even the medical journals are continually filled with warnings of the dreadful consequences following the uses of the *x*-ray, mostly published by men whose knowledge of *x*-ray therapeutics at best is very limited. There is no denying that there is a certain element of danger, and in inexperienced hands this danger is considerable, but on the whole, in experienced hands the therapeutic application of the *x*-ray is comparatively safe.

In a paper read by me before the last International Dermatological Congress, among other things I reported 225 cases of eczema treated with the *x*-ray at the Mount Sinai Hospital (Dr. Lustgarten's Clinic) with generally good results. This report has been attacked by Gottheil* on the grounds that he gets as good results with medication alone, and he sees no excuse for submitting patients to the great danger of *x*-ray exposures for dermatoses of this type. It is gratifying to know that there is at least one man who has succeeded in curing all his cases of eczema without the aid of an adjunct such as the *x*-ray.

I must candidly admit that our results in treating eczema have been much improved since we have resorted to *x*-ray therapy in our stubborn cases. Dr. Gottheil is evidently laboring under the misapprehension that we use the *x*-ray on every case of eczema that comes into the Clinic. Such is not the case. In practically all of the 225 cases I cited medication alone was tried for a while, and only when the disease was found to be very stubborn were they submitted to *x*-ray treatment. A large number of these cases came to us with a history of having been treated in different Clinics for a considerable time without relief. Under these circumstances we felt justified in resorting to this (according to Gottheil) extremely dangerous measure, I am happy to say without any accidents. To expect good results one must be somewhat conversant with the proper technique of its application.

It is important to shield every part of your patient, except the area of the lesion. The tube used should be a medium vacuum tube; if it is too low, you are apt to produce a dermatitis too easily; if it is too high, you will not have a sufficient amount of therapeutic rays. The time of exposure should depend upon the intensity of the ray, the degree of vacuum of the tube, the distance of the patient from the ray, and the amount of surface exposed.

For an ordinary case, take a middle vacuum tube, with a fairly intense ray, the patient about 6 inches from the tube, a not too large area exposed, probably 5 minutes would be an average exposure. This could be given about two or three times a week.

Of course, a great deal will depend upon the patient's idiosyncrasy, the severity of the case, and a large number of other factors. While in the majority of cases the *x*-ray alone would suffice to bring about a cure, I have had the best results from combining this treatment with the various forms of medication previously described.

In giving you the treatment of eczema, I wish to draw your attention to the fact that I have made no effort to review the innumerable suggestions made by different authorities, many of which are probably very good, but I have simply attempted to give you an outline of the treatment which I am carrying out in private and hospital practice with what I regard as very good results.

TWO CASES OF CANCER TREATED WITH TRYPSIN.

SUPPLEMENTARY REPORT.

By F. B. GOLLEY, M.D.,

MILWAUKEE, WIS.

Some time ago I reported two cases of cancer under treatment with injectio trypsini and noted the effect up to the time of the report. One was a case in which the disease was located in the vagina posterior to the uterus, extending up into the pelvis, in a woman of middle life. The other was in an older woman in whom a large fungous mass filled the caliber of the bowel and distended it to such an extent that the pelvis was nearly blocked with the growth, and several other surgeons did not consider its attempted removal judicious.

The first patient can be disposed of in a few words. She is in fairly good health, and considers herself cured, although I suspect at some future time she will have more trouble. At this writing she is free from pain, the surfaces are all healed, and she is about her duties as if perfectly well.

Since the first report of the second case I have obtained possibly a more connected history of the trouble, completing the clinical picture of the disease from its outset to the final scene a month ago. The reader will bear in mind that this patient was a large, powerful woman of remarkable energy and will power. Between six and seven years ago, she had some bowel trouble and pelvic uneasiness. She concluded it was hemorrhoids and consulted a rectal specialist who injected some of the larger veins about the anus. She dismissed the trouble from her mind for months, after which she did not feel just right, and in due time, I believe about a year from the first treatment, she had the process repeated. The same was done again, once or twice, at about the same intervals. Conditions now continued to get more troublesome; the discomfort was increasing, and the usual vigor began to wane.

She again consulted the specialist, late in the year 1905 or early in 1906, and at this time he suggested that the hemorrhoids were not causing all the trouble. She then came to me, but concluded to be examined later; this she did some time early in 1906 and the condition previously outlined was found.

After she had been examined by others and operative measures had been advised against, she returned to me for whatever treatment seemed expedient. She had learned of the injection method and wished it tried. After a six weeks' course of injections she went to the Pacific Coast for several months. Immediately upon taking the treatment her general physical condition improved wonderfully. In fact, she was her old self again, as she expressed it. In the fall she concluded to resume the injections, though she had no examination to verify the results beyond her own feelings, being decidedly averse to anything of the kind. I persuaded her that it would be more in line with good judgment to know what the conditions were, and the probable results of further measures for relief. Upon examination shortly before the holidays a peculiar and desirable condition was found. The caliber of the bowel which had been distended by the growth to a great extent was still large, but in place of a soft fungous mass there were large patches of seemingly healthy membrane, studded over with hard (extremely hard) scirrhous nodules varying in size, but averaging about the diameter of a silver quarter. These nodules were mostly covered with membrane. There was no evidence whatever of the former growth, except the large flattened caliber of the bowel and resultant nodules. This condition of tissue continued from the fall of 1906 to the summer of 1908 when the patient died. Some patches evidently broke down sufficiently to allow of coloring of discharge, but at no time was there any hemorrhage. During all of this time the bowels moved with little aid and not much pain up to the last three months. The suffering was nothing like that usually experienced in such cases.

Treatment by injection of trypsin was continued at intervals up to June, 1907. After that she did not use more. Even up to the last there was marked influence over the general physical condition whenever she would consent to its use.

From close observation of the case there seem to me to be three important items worthy of mention.

1. It never became necessary to establish an artificial anus either for relief of pain from fecal presence, or because of stoppage in the bowel.

2. The character of the disease changed from an active and rapidly progressive type, to a slow and practically stationary one, which not only prolonged life, but shut off the disease from outside irritative influences, making life more bearable and wholesome, by the formation of membrane over the raw surfaces. In short, replacing an active, loathsome disease by one more endurable.

3. It seems to me that trypsin exerts some influence upon the metabolism of the general system, and of course indirectly upon the growth. It is a self-evident truth that if the organism could be maintained indefinitely at a sufficiently high standard, it would not only not be subject to the onslaughts of disease, but would live on for all time. It is upon this element, to a very moderate degree in my opinion, that depends whatever influence the trypsin treatment has over cancerous growths. Somehow it influences the metabolic processes particularly and establishes a resistance to the cell activity of malignancy. Further than this I have been unable to locate a reasonable hypothesis for its peculiar action. I would conclude then that it might be a valuable adjuvant to other recognized procedures in the management of cancerous cases.

150 Grand Avenue.

WHOLESALE BABY WASHER.

By W. P. Northrup, M.D.,

New York,

Attending Physician, Presbyterian Hospital.

Given a cold ward, sixteen to twenty babies to wash every day, danger of infection from promiscuous tubbing, and a wish to save time and promote comfort. The wards of the Presbyterian Hospital are 65° F. by day and 60° F. by night.

Wanted (1) A warm washing, dressing, and changing-room (by us familiarly called) "grooming-room," with atmosphere warm (75 F. and more), furniture, walls, and floor warm; fresh clothing, diapers and towels warm; water warm—in short, everything warm.

(2) Facilities for washing and dressing, *i. e.* "grooming" infants, comfortably to the nurses as well as to the babies, and in the shortest possible time.

(3) Assurance that all this may be accomplished for an indefinite period without burning a single baby. The outfit in this respect must be "fool-proof."

Found: Successful facilities and appliances (see illustration). Beginning above, one sees an eighty-gallon tank; the water heated at will, usually to 103° F. The temperature is read off on the thermometer projecting from the left of the lower quarter. This tank is filled by the same nurse each day, the temperature noted by the head nurse and the hot and cold intake pipes shut off till further orders. This insures a constant temperature (103° F.) in the tank and about 100° F. as it runs from the spray. The water gauge shows on the face of the tank. In this glass tube the amount of water in the reservoir can be easily noted. Mixing the hot and cold water is effected as follows: The hot and cold water pipes are turned on together while the filling and temperature are noted by the nurse deputized for this purpose. The hot and cold water pipes within the tank terminate in four points somewhat like a miniature gas-fixture, the hot water tips pointing downward, the cold water pipes pointing upward. The current of the two streams goes against their gravity tendency and so interdigitate that a thorough intermingling of currents is effected, and there can be no layers of hot and cold water. The contained water is of uniform temperature throughout. Eighty gallons is found to be enough to serve for a morning's work. There are overflow pipes.

Below the tank are seen two flexible rubber pipes terminating in the usual metal bath spray tips. From these, it is designed, that the water shall flow at 100° F. uniformly during the entire morning's work.

On the next lower level is seen a sink winged with two sloping marble slabs. These slabs are warm and upon them are laid individual bath towels and the baby. After each bath the towels are boiled.

To the extreme right is seen the hot closet from which the fresh clothing is taken dry and hot.

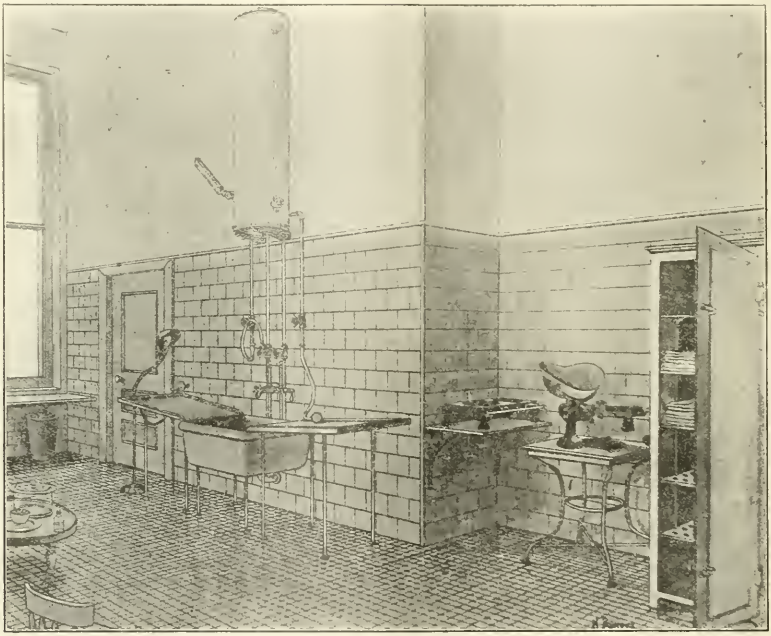
At the extreme left are seen the low nursery tables and chairs found convenient in dressing the children.

It is noted that a very large window lets in a flood of light so that the slightest eruption or change of color or abnormal appearance of the mouth, tongue, or eyes can be easily detected. An electric reflector in addition to the overhead lights serves the same purpose at night. There are two doors, one leading to the corridor and one (that shown in the illustration) to the toilet.

Result: After several months' use, the apparatus and general facilities of the room have proved satisfactory.

(1) The babies are washed in less than half the usual time.

(2) The babies seem to be more comfortable and happier during bathing. They seem thoroughly



"Wholesale Baby Washer," Presbyterian Hospital, New York.

to enjoy the warm room and warm spray; they wriggle and gurgle and crow.

(3) Danger of infection from promiscuous tubbing is avoided.

(4) Mishaps from the use of over hot water are thus far avoided and it would seem that the chances are reduced to the minimum. As a general proposition one is painfully conscious that it is always possible for novitiates, excited individuals, mothers, and doctors, as well as nurses, to have mishaps, with unfortunate results, in the combination of baby and hot water bath.

The present facilities, above described, are the result of much studious attention on the part of the heads of the various hospital departments. The results so far, after a trial of several months' duration, justify us in recommending the apparatus and general facilities of the "wholesale baby-washer."

Sudden Death in Scarlet Fever.—A. Gouget and Dechaux state that sudden death may occur at any time in scarlet fever, and the explanation is not easy. At the very beginning of the disease, even before the eruption has appeared, or there is any angina, in the malignant form of the disease death may occur. In the midst of perfect health vomiting, diarrhœa, delirium, and convulsions may begin, and end in death in a few hours. In these cases diagnosis, except in the presence of an epidemic, is very difficult. In other cases the disease begins as usual, and the only disquieting symptom is a thready pulse, very frequent. Finally sudden death may occur in the midst of convalescence, with sudden vomiting, delirium, frequent pulse and death in convulsions. Sudden death is not uncommon in the nephritic stage of scarlatina. The question is how to explain these cruel surprises. Autopsy gives us no help, since nothing has been found to account for death. The only explanation is that of an extreme degree of intoxication, which overwhelms the nervous system or heart. According to some, there is a lesion of the suprarenals. But examinations of these glands in scarlet fever have given no light as yet. According to others, they occur in those who have been overfed.—*Presse Médicale.*

Diabetic Families of Children.—G. Lion and Ch. Moreau cite their personal observation of a family in which three children were successively attacked by diabetes and all of them succumbed. They have collected thirty examples of such families, which have been published, of which histories are given. This disease seems to have an element of heredity in its causation. The exciting cause is not generally to be found, although emotion or fright seem to have been the beginning of the attack. The course of the disease is progressive and rapid, some cases ending in from a few weeks to eight months, while others last as long as three years. Those not attacked in childhood are very apt to show the disease in adolescence. There is not a typical picture of diabetes at first, and the general health is not at first affected. Thirst is the first sign noticed, and sugar may be the only thing noticed and be accidentally discovered. Treatment may for a time lessen or remove the sugar, but as soon as the diet of milk is stopped the sugar reappears, and cachexia begins sooner or later, and goes on to emaciation, somnolence, and death, in coma. The prognosis for the individual case is bad, and when one member of a family has been attacked the prognosis for the other members is bad.—*Archives de Médecine des Enfants.*

New York, May 8, 1909.

THE CHURCH AND THE EMMANUEL MOVEMENT.

AT a special masonic service, held last Sunday evening in Calvary Episcopal Church in this city, the anthem, composed by the accomplished choir master, Mr. Arthur Lacey Baker, was in the form of a protest against Christian Science. That its meaning should not be mistaken, it was "respectfully dedicated to Mrs. Mary Baker Eddy," but one thus enlightened, on hearing it, could not fail to interpret it as a warning also to churchmen not to be misled by the teachings and practices of that first cousin to Eddyism, the so-called Emmanuel movement. The theme of the anthem is sustained by the soloist while the chorus confirms and explains the warning. The baritone begins:

O Earth, Earth, hear the word of the Lord.
Be thou instructed, O Jerusalem, lest my soul depart from thee.
Shall a man make gods unto himself and they are no gods?
I hearkened and heard, but they spake not aright.
They are vanity and the work of errors.
Deceive not yourselves Ye looked for peace and no good came, and for a time of health, and behold, trouble.

Then the Chorus affirms:

The way of man is not in himself: it is not in man that walketh to direct his steps.

The soloist continues:

O ye priests! How long will ye sit still?
Who is this that darkeneth counsel by words without knowledge?
How do they say, "we are wise and the law of the Lord is with us?"
Thus saith the Lord of hosts, Lo these have rejected the word of the Most High, and what wisdom is in them?
For they have healed the hurt of my people slightly, saying, "Peace, peace," when there is no peace.

* * * * * * * * *

In thy sickness give place to the physician, for the Lord hath created him and given him skill, that he might be honored in His marvellous works. Let him not go from thee, for thou hast need of him.

Of the Most High cometh healing. He hath created medicines out of the earth, and he that is wise will not abhor them.

The Chorus then explains that "love and might no longer heal by touch, or word, or look," and that they who do God's work must read His laws in nature's book; and the soloist makes a final appeal:

How long halt ye between two opinions?

And the Chorus affirms:

As for me and my house, we will serve the Lord.

Serving the Lord in time of sickness, according to this ecclesiastical poem, is to turn for help to the physicians whom the Lord hath created and to be healed by the medicines which "He hath created out of the earth" and which the wise man will not abhor. It is encouraging to see that the Church will not let this new heresy grow and flourish without opposition, and indeed this is not the first protest which has been heard within an Episcopal church against the dangerous meddling with disease by clergyman of that and other denominations. The Rev. Mr. Werner of Grace Episcopal Church, Norwalk, Conn., preached a powerful sermon against the Emmanuel movement on St. Luke's Day, 1908, and other clergymen have also warned their flocks against it.

Now that the novelty of the movement has begun to wear off and the arguments in its support are being critically considered, its utter illogicality is becoming more apparent. The attitude of the Catholic Church toward divine healing is logical and, assuming its premises, perfectly sound and reasonable. It regards healing by faith and prayer as frankly miraculous, and believing that God will at times, in response to the prayer of the faithful, suspend the action of natural laws, it sees no reason why cancer and tuberculosis may not be cured by faith, as well as neurasthenia or a bad temper. But the Protestant churches hold that the age of miracles is past, and when they resort to extramedical healing they must restrict its action to functional diseases, to maladies without physical basis. But they do not define functional diseases in an intelligible way, and in their attempts to delimit this class of diseases they flounder about in the theory of the subliminal self, without rime or reason. As a witty physician said at a medical dinner last winter, they simply take an autosuggestive pill and get an Emmanuel movement.

It is a healthful and hopeful sign that many earnest churchmen are beginning to look askance on this sensational and harmful meddling of clergymen with pathology. They see that true religion and Eddyism, real or bastard, are incompatible and that the attempt to amalgamate them will only corrupt religion. It will be a sad day when men take to religion, as they might to politics, for "what there is in it" in the way of health or pocket.

THE SCIENTIFIC ASPECTS OF THE CONSUMPTION OF ALCOHOL.

THE last word in regard to the alcohol question has by no means been said. It is true, that in the main, the results of experiments made in this country, in Germany, and in England, in order to determine the effect of small doses of alcohol have been against its use, but these experiments, perhaps, have not been sufficiently conclusive to warrant the statement that alcohol under all circumstances is harmful. Of course it cannot be denied that the general trend of medical opinion is adverse to the employment of alcohol, and this change of front is plainly shown by the fact that hospitals now use far less alcohol than was formerly the case. Many authorities hold that total abstinence from beverages of a stimulating character is the most healthful procedure for everyone,

and especially so for brain workers. The late Professor Huxley declared: "If a man cannot do brain work without a stimulant of any kind he had better turn to hand work. It is an indication on Nature's part that she did not mean him to be a head worker."

Sir Victor Horsley, the well known British authority on brain surgery is violently opposed to stimulants, and has frequently voiced his views that under any conditions alcohol is a veritable poison, and there are many more men of the highest scientific rank in all civilized countries who are of the same opinion. It is stated that the power of memory is weakened by even a small quantity of alcohol. For instance, the experiment has been tried of reading over to individuals a number of names or figures until they remembered them, and it was found that the individuals who did not take alcohol remembered one hundred figures or names in their right order after having them called over forty times, but that on the days when alcohol was given them they could repeat only sixty words aright after they had heard them read sixty times. Experiments have likewise been carried out in connection with rifle shooting, and a number of men were found to make 30 per cent. more bull's-eyes at a rising target when they had not taken any alcohol as compared with what they made when allowed alcohol. It is argued by hard and fast abstainers, that both the nervous system and the circulation are injuriously affected by taking alcohol in quite small quantities, and that indeed all the powers and functions of the human body are injured by its moderate use.

Before accepting all the statements made by those who are opposed to the use of alcohol and who deny that it possesses medicinal value, it may be as well to review a few of the facts marshalled on the other side. All are agreed that alcohol to excess is harmful, and that the drink habit has had much to do with the obvious degeneration that has taken and is taking place in overcrowded civilized countries, but this does not prove that alcohol is injurious under all and any circumstances. An excessive meat diet undoubtedly has a more injurious effect on the blood-vessels than too much alcohol, and it seems likely that alcohol has a value from the psychological point of view. Moreover, a patient recovering from a serious and debilitating illness who has lost appetite for food has, in many instances, appeared, at any rate, to have derived great benefit from the judicious employment of alcohol given in palatable form.

Again, the idiocyncrasy of the individual must be taken into account. There are certain drugs which affect some persons in one way and other persons in an altogether different way, or scarcely affect them at all. There are men and women to whom alcohol is a deadly poison and there are human beings on whom stimulants seem to have a beneficial effect. But, probably, it is still more a question of immunity. A race, for example, like the British race, living in a somewhat cold, damp climate, and which has for generations been addicted to the use of alcohol, acquires a considerable degree of immunity, and really it looks as if, on the whole, the race has not suffered to the extent which, if alcohol is so deadly as its opponents assert it to be, it should have suffered.

In the case of brain workers, alcohol is contraindicated. An individual who leads a sedentary life and who makes large calls on his mental faculties does not require the spur which may, at first, be found in stimulating beverages. It should always be borne in mind that alcohol is a narcotic and that although its primary effect is of a stimulating nature, it really dulls and in large doses deadens the central nervous system. To some of those who lead a vigorous out-of-door life, and who do not rely wholly on their brains for their livelihood, alcohol in moderation apparently does little or no harm. As a medicine, although its value is not so widely recognized as of yore, it yet cannot be said that it is worthless. The same remark may be applied to the value or otherwise of alcohol as a food, for if it is valuable as a food it must be valuable as a medicine.

The opponents of alcohol, even those who argue against it on scientific grounds, and whose scientific attainments render their arguments weighty, seem to an unbiased observer to be apt to go somewhat too far. Experiments and experience certainly have shown that alcohol is not the valuable drug that it was formerly considered to be, but neither have they shown that it is a deadly poison to be absolutely avoided. Experience has demonstrated clearly that the unguarded and indiscriminate use of alcohol is a terrible evil which should be combated in every way possible. If the harm that alcohol has wrought were to be reckoned against its value, little doubt can be felt as to what the verdict would be, and it might be for the good of mankind at large if it were totally abolished. Regarding the matter, however, from the cool and dispassionate scientific standpoint, the case against alcohol as a food or a drug, while it is strong has not as yet been proved absolutely. In the course of a few years, or less, the final decision may be reached, but until that time arrives it will be unwise to be too confident in one direction or another.

SHELLFISH AND TYPHOID FEVER.

Although the earliest outbreak of typhoid fever attributed to the eating of oysters was reported in 1816, and especially since 1880 many other cases have been placed on record, but little is as yet known positively upon which a determination of the sanitary conditions of shellfish can be based. Nor has there yet been established a definite relation between any estimated pollution of water or of shellfish and the disease-producing liability of such polluted water or shellfish. The evidence connecting the eating of polluted oysters with outbreaks of typhoid fever cannot, however, be questioned. In the United States the most notable examples of such epidemics were those at Middletown, Conn., and at Atlantic City. The Monthly Bulletin of the New York State Department of Health in reviewing the subject refers to the conclusions of

the British Sewage Disposal Commission. This commission concluded that a considerable number of cases of enteric fever are caused by the consumption of shellfish which have been exposed to sewage contamination, though an accurate determination of the number of such cases was naturally not possible.

That pollution of tidal waters with undisinfected discharges from typhoid fever patients does occur, in spite of the efforts of physicians and health officers, is undisputed, and it must be remembered that the discharges from convalescents are in some cases as dangerous as those from patients in the active stages of the disease. The probability is that the greatest danger lies in the improper disposal of the excreta of one or two specific cases rather than in the presence of a large amount of sewage, though estimation of the disease-producing power of any infected water, or shellfish from such water, is not possible by present laboratory methods. The most careful studies and investigation of actual conditions are necessary before any positive condemnation or trustworthy certification of oyster beds can be made.

Such an investigation is now being carried on by the State Board, and data are being secured as to the pollution of the streams, tidal waters, etc., in the waters adjoining Long Island and Staten Island, which comprise the oyster cultivation districts in this State. The location and extent of all beds have been mapped out; visits to the beds have been made; and 128 samples of water and 204 samples of oysters have been examined bacteriologically. The results of the studies in the field and in the laboratory are in accord; but the work is still preliminary and the Department is not yet prepared to pass judgment. That unrestricted pollution of the waters of the State should cease, is, however, evident; and the policy of the Department of Health in preventing, in so far as it has the power, the discharge of raw or ineffectively treated sewage into these waters, will be continued and extended.

Pyelocystitis in Infancy.

Digestive disturbances of infants have been so exclusively studied lately that frequently they are taken as the primary disease in cases in which they simply accompany some other underlying condition. One such condition is the inflammation in infants of the urinary tract, from the bladder to the kidneys, to which Göppert devotes a very instructive paper in the *Berliner klinische Wochenschrift* for April 5, 1909. As is usually the case in young children, the disease may begin with symptoms simulating an affection of almost any system of organs; acute gastroenteritis, acute pulmonary inflammation of whatever nature, or a meningitis may at first be suspected. The true nature of the disease is disclosed by an analysis of the urine, a procedure which is altogether too often neglected in the routine examination of a sick child. The urine in such cases is usually foul smelling, contains albumin and a variety of bacilli, the predominating organism, however, being *Bacillus coli*, to which the disease is probably due. The temperature curve and the course of the disease usually answer the picture of sepsis, the severity of the symptoms differing, of course, with the extent of the lesion, and the natural powers of resistance of the individual child. Early diagnosis is the most important part in treating the disease, for when the attention is distracted by the accompanying digestive disturbances, the infection progresses until the kidneys and then the whole organism are involved. Once the disease is recognized, its treatment is simple, consisting in forcing of fluids, so as to wash out the infected parts and in the administration of alkalies and of urinary antiseptics in order to inhibit the growth of the colon bacillus. If treated early the mortality is not very great when the usual dangers of all diseases of infancy are remembered. Late cases, however, always do badly, the organism being rapidly overwhelmed by the infection. Now that attention has been called to the comparative frequency of the affection, its early recognition and consequently its proper treatment will probably follow more often than heretofore.

A Substitute for Bismuth in X-Ray Work.

Bismuth was formerly looked upon as a very harmless remedy that may be given in large doses without untoward results, although its possible toxic action has always been known. Especially large quantities of this substance have been administered lately since the discovery that after such administration complete shadows of the gastrointestinal canal may be obtained in *x*-ray pictures, which fact has, of course, been utilized in the diagnosis of disease. However, a number of cases of poisoning have been reported since the introduction of this practice, and in the *Münchener medizinische Wochenschrift* for March 30, 1909, no less an authority on drugs than L. Lewin recounts a number of untoward conditions which may result from large doses of this remedy. Among them he names dark discoloration of the tissues in the mouth and in the deeper parts of the gastrointestinal canal, such discoloration remaining for weeks in the gums, for instance. Inflammation of the buccal mucosa may occur, followed by salivation, loosening of the teeth, swelling of the tonsils, etc. Functional disturbances of the stomach and intestines are quite frequent, while more important still are the changes produced in the kidneys, resulting in albuminuria, or even desquamative or parenchymatous nephritis. As other salts of bismuth are in Lewin's opinion just as toxic as the subnitrate, he has experimented with different preparations that could prove acceptable as far as *x*-ray photography is concerned and yet result in no dangerous effects upon the organism. Ferric oxide was found to fulfil these conditions perfectly and is therefore recommended by the author. It may be administered as a mixture with potatoes or with chocolate. Experiments with animals proved that the drug was quite free from any untoward action, while *x*-ray pictures of the human gastrointestinal canal, taken after administration of large amounts of this preparation, were much clearer and more useful for diagnosis than those taken after salts of bismuth had been given. Lewin promises to publish a series of cases in which his preparation was used, and the *x*-ray examination of internal hollow organs has become so frequent recently that his publication will be awaited with interest by both practising physicians and röntgenologists.

News of the Week.

Army Medical Corps Examinations.—The Surgeon General of the Army announces that preliminary examinations for appointment of first lieutenants in the Medical Corps of the Army will be held on July 12, 1909, at points to be hereafter designated. Full information concerning the examination can be procured upon application to the "Surgeon General, U. S. Army, Washington, D. C." The essential requirements to securing an invitation are that the applicant shall be a citizen of the United States, shall be between 22 and 30 years of age, a graduate of a medical school legally authorized to confer the degree of doctor of medicine, shall be of good moral character and habits, and shall have at least one year's hospital training or its equivalent in practice. The examinations will be held concurrently throughout the country at points where boards can be convened. Due consideration will be given to localities from which applications are received, in order to lessen the traveling expenses of applicants as much as possible. The examination in subjects of general education (mathematics, geography, history, general literature, and Latin) may be omitted in the cases of applicants holding diplomas from reputable literary or scientific colleges, normal schools or high schools, or graduates of medical schools which require an entrance examination satisfactory to the faculty of the Army Medical School. The recent Act of Congress giving an increase in the Medical Corps, together with a larger regular army, will permit of a great variety of medical and surgical work, besides affording opportunities for those specially qualified to engage in special work, such as surgery, sanitation, chemistry, pathology, microscopy, and bacteriology. All appointments are made with the rank of first lieutenant ($2,000 per annum). At the end of three years the officer is promoted to captain at $2,400, which, at the end of five years' service, is increased to $2,640, etc. In addition to this, officers are furnished with quarters, medical attendance, and medicines for themselves and their families, the privileges of the commissary, mileage at the rate of seven (7) cents per mile when traveling under orders, and allowed one month's leave per year with full pay, which may be allowed to accumulate to a maximum of four months; also the privilege of retirement. These allowances are estimated to add from $1,200 to $1,600 to the yearly compensation in the grades of First Lieutenant and Captain. In order to perfect all necessary arrangements for the examination, applications must be complete and in possession of the Adjutant General of the Army on or before June 10, 1909. Early attention is therefore enjoined upon all intending applicants, and free correspondence with the Surgeon General's Office is invited on any subject connected with the examination. There are at present 103 vacancies in the Medical Corps of the Army.

The American Confederation of Reciprocating, Examining, and Licensing Medical Boards.—The annual meeting of this Confederation will be held at Louisville, Ky., on May 12, 1909, at 10 A.M. Several important subjects will be taken up at this meeting, including medical curriculum and reports from committees on constitution and minimum standard of preliminary education for entrance to recognized medical colleges. State Medical Boards in membership should be represented at this meeting by their executive officers or accredited members. Medical Boards which have adopted methods of interstate endorsement of medical licenses, but are not in active membership, are invited to send representatives, as well as those Boards the members of which believe in the principle of reciprocity and intend taking the matter up practically in the future. There are at present some thirty-five States which have adopted practical methods of interstate medical reciprocity, and the advisory standards and methods in force by the Confederation are being generally adopted by such States. It is, therefore, most important that every Board should be represented at this meeting, and accredited representatives are urged to be present. Membership in the Confedration is confined to State Medical Boards, but educators interested in the work of the Confederation are invited to be present, and will receive the courtesy of the floor.

Bellevue Training School.—Following the graduating exercises of the training schools for nurses of Bellevue and Allied Hospitals, New York, on April 28, at which diplomas were awarded to twenty-seven women and nineteen men, the new Residence Hall for Women Nurses, at 440 East Twenty-sixth street, was dedicated by Mayor McClellan. The new home has been built by the city at a cost, including the land, of nearly one million dollars. It contains on the ground floor large lecture rooms, reception room, dining-room, and kitchens. The five floors above are given over to dormitories, in which there are 300 bedrooms. The central portion of the roof is occupied by a roof garden and pergola. Work on the building was begun in 1906, and has been part of the general scheme for the enlargement of Bellevue Hospital. The old nurses' residence is to be made over, enlarged, and turned into a graduate nurses' club house. It is hoped that the building of a similar residence hall for the men nurses may soon be made possible. At the graduating exercises addresses were made by Dr. John Brannan, President of the Board of Trustees of the Hospital, and by Dr. John H. Finley, President of the City College, and the diplomas were presented to the women nurses by Mrs. W. C. Osborne, and to the men nurses by Dr. W. K. Draper.

Hospital Saturday and Sunday Association.—The Distributing Committee of the Hospital Saturday and Sunday Association met at the City Hall, New York, on April 30, and apportioned the funds collected during 1908. The apportionment is made according to the free work done by each hospital, with the proviso that no institution shall receive less than $250 or more than 10 per cent. of the entire fund. The fund for the year amounted to $72,000, and the Montefiore Home and Mt. Sinai Hospital had the largest awards, each receiving $7,200.

Gifts to Charities.—St. Joseph's Hospital of Syracuse and St. Joseph's Hospital for Consumptives of New York receive an income of $200 a year each, for ten years, by the will of the late Peter F. Collier.

By the will of the late Henry Harmer of Philadelphia a contingent bequest of $3,500 is made to the Home for Consumptives at Chestnut Hill.

By the will of the late George C. Thomas of Philadelphia bequests are made to Hahnemann Medical College and Hospital and the Episcopal Hospital of $10,000 each.

By the will of the late Fannie R. Shoemaker of Philadelphia her residuary estate, amounting to about $25,000, is devised for equal division among the Episcopal Hospital, the P. E. City Mission, the Philadelphia Home for Incurables, the P. E. City Mission for the Home for Consumptives, and the Sheltering Arms.

By the will of the late Edward N. Benson of Philadelphia the sum of $50,000 is bequeathed to the Pennsylvania Hospital, $10,000 to the Children's Bethesda Christian Home, and $10,000 to the Chestnut Hill Hospital.

By the will of Miss Elizabeth Brigham, sister of the late Robert Brigham of Boston, $1,500,000 is given to the Robert B. Brigham Hospital for Incurables, for the founding and maintenance of which the brother left the bulk of his large fortune.

Public Health in Illinois.—At the public health conference, held at the University of Illinois, Urbana, April 23, the following resolutions were adopted: (1) That an annual conference of health officers should be held in the State of Illinois, to provide for the instruction of health officers in recent advances of science and of practical experience related to the public health, for the free discussion of public health problems in the State, and for the expression of opinion by the assembled health officers on methods of promoting the public health and related subjects. (2) That the State University be asked to provide opportunity for more systematic investigation and more comprehensive instruction in hygiene, sanitary science, and the science related thereto. (3) That a committee of three be appointed by the Chair to present to the University and to the State Board of Health a plan for carrying out the suggestions made in the above resolutions, and to render assistance in securing the necessary legislation.

Death Rate from Tuberculosis.—Twenty-six cities in New York State showed a smaller death rate from tuberculosis in 1908 than in 1907, New York, Troy, and Schenectady among them. Troy, however, still has the highest rate of deaths from this cause, with Albany second, and New York third. Increases were noted in Buffalo, Rochester, and Yonkers, but these are probably due to more accurate records. An increase was also noted in many of the rural districts.

Epidemic of Measles.—An outbreak of measles has occurred on the receiving ship *Wabash* at the Charleston Navy Yard. A number of patients have been sent to the Chelsea Naval Hospital, and the ship has been quarantined.

Amendments to Sanitary Code.—Two amendments to the Sanitary Code of the Board of Health, New York, were put into effect on May 1. One provides that cream, sweet or sour, sold in the city, must contain at least 15 per cent. of butter fat. The sale of sour cream is permitted as in some of the foreign quarters it is considered a great delicacy. The other amendment concerns the covering of garbage receptacles.

Summer Medical School.—The medical department of St. Louis University will conduct a summer medical school, beginning on May 24 and continuing until July 24. The course will be for graduates and practitioners, and to it women will be admitted on the same terms as men. The University has also announced that beginning with the term 1909-10, the course in medicine will be increased to five years, and high school diplomas or their equivalent will be necessary for admission.

New York Diet Kitchen.—The work of this institution has been extended to include the provision of certified milk for tenement babies at the price of six cents a quart. The milk will be furnished only on a requisition from a physician or some one of the charitable organizations cooperating with the Diet Kitchen. In previous years the work of the Diet Kitchen has been confined to those unable to pay for food for their sick, though it has recently been broadened to include instruction in the preparation of babies' food by the visiting matrons.

Cost of Antivivisection Campaign.—The New York Antivivisection Society has certified to the Secretary of State that it expended $941.75 on the proposed legislation during the present session of the Legislature. The society opposed the Davis-Lee bill and favored the passage of the Brough-Murray bill, neither of which was acted upon by the Legislature.

Centenarians.—Mrs. Esther H. Patterson died at Philadelphia, on April 9, at the age of 102 years. From Tennessee comes the news of the death of Jesse Jones, colored, who claimed to be 115 years of age, and to have fought in all of the important wars of the United States since 1812. Mrs. Fannie Friedman, who died recently in New York, was said to have passed her 112th birthday. She was born in Hungary, was married before she was twenty-one, and had thirteen children. At the time of her death she had eighty-two living descendants. Her rule for good health and a long life is said to have been: "Don't worry; take things easy; sleep ten hours a day, and eat five meals." Viewed in the light of her experience, the rule is certainly as well worth following as those of some younger philosophers, whose eating and sleeping allowance is less liberal. Simon Bildstein, who celebrated his 100th birthday in St. Louis on Sunday of this week, attributes his long lease of life to the fact that he is a philosopher and never worries. The newspaper report of his birthday celebration says that he smokes, chews, and drinks without stint. His regular consumption of whiskey, according to this statement, is one gallon a week.

Harvard Medical School in China.—The Harvard Mission, a body connected with the Young Men's Christian Association and the Harvard Medical School, has in contemplation a plan for establishing a medical school in the Orient, probably in China. For several years such an institution has been in prospect, and the preparations have now reached the appointment of a board of trustees and enlistment of volunteers. The institution will have no affiliation with any missionary or religious organization. Dr. M. R. Edwards will probably go to China this summer to look for an available site.

The Mary Gates Hospital.—The hospital which Mr. John W. Gates is to erect at Port Arthur, Tex., in memory of his mother, is to receive an endowment fund of $500,000. To this will be added each year two per cent. of Mr. Gates' profits from oil, which it is estimated will amount to between $2,000 and $5,000.

Report of Mercy Hospital.—According to the annual report of the Mercy Hospital, Chicago, for the fiscal year ending April 1, 1909, the number of patients received there during the year totalled 3,435. Three thousand one hundred and thirty-two

patients were discharged as cured, 162 died, leaving 141 patients still in the hospital. Of the cases treated, 563 were medical, 2,392 surgical, 219 gynecological, 106 obstetrical, and 155 ophthalmological and otological.

A New Dispensary.—Adjacent to the Mercy Hospital by the Northwestern University Medical School an addition known as the Calumet Avenue Branch of the South Side Dispensary has been erected, at a cost of $30,000. In this building are a large faculty room, two recitation rooms, thirteen small examining rooms, drug rooms, a photographic room, an *x*-ray room, all these being on the first floor. The entire rear of the floor is occupied by laboratories. On the second floor there is an assembly hall for clinical demonstrations, with a seating capacity of 300.

Fire at Sheldrake Springs.—On the night of April 20, the power plant at Sheldrake Springs, on Lake Cayuga, was destroyed by fire, causing a loss of $10,000. Fortunately no damage was done to the main building, and arrangements were made within two or three days for supplying water, heat, and light, so that no serious inconvenience in caring for patients resulted. A new and fireproof power plant is now under construction.

Vacancy at Bellevue.—A vacancy exists at present in the position of Attending Surgeon to the Fourth Division of Bellevue Hospital. The trustees have adopted a rule in accordance with which no one herafter occupying the position of attending physican or surgeon on the Fourth Division shall be at liberty to affiliate himself with any of the three colleges (Columbia, Cornell, New York University) now having teaching connections at Bellevue Hospital. Applications for the position should be made without delay to Dr. Cyrus J. Strong, Secretary of the Medical Board, 60 West Seventy-fifth street, New York.

The Fordham Hospital.—Several vacancies exist on the staff of Fordham Hospital, Out-Patient-Department. Applicants can obtain proper application blanks from the secretary, Dr. Alexander Nicoll, 123 West Seventy-fourth street, New York City.

The Brooklyn Memorial Hospital.—Founded twenty-eight years ago for the treatment of women and children, this institution was closed on April 30, pending the erection of a new building. The frame building on Sterling place which has been occupied by the hospital will be used for a dispensary, a single bed being kept for an emergency.

St. Luke's Hospital Alumni.—The annual dinner of the Society of the Alumni of St. Luke's Hospital, New York, was held at the Yale Club on April 30. Addresses were made by Dr. F. C. Wood, who outlined the plans for work in the new chemical laboratory at the hospital, and by Dr. F. S. Meara, whose subject was Medical Education in New York. The society elected the following officers for the ensuing year: *President*, Dr. C. T. Dade; *Vice-President*, Dr. E. H. Rogers; *Secretary*, Dr. Karl M. Vogel; *Treasurer*, Dr. J. B. Squier.

Cautious Montclair.—The Board of Health of Montclair, N. J., has recently adopted a rule requiring that every loaf of bread sold in the town shall be delivered to the consumer in a sealed aseptic paper bag.

Lecture on Cancer.—Dr. William Seaman Bainbridge will deliver the fifth annual lecture on malignant disease, with the presentation of patients, in the out-patient hall of the New York Skin and Cancer Hospital, Second avenue and Nineteenth street, New York, on Wednesday afternoon, May 12, at 4.15 o'clock. The lecture is free to the medical profession.

Dr. Theobald Smith of Harvard University addressed the members of the Cumberland County (Maine) Medical Association, at Portland, on April 17, on "The Relation Between Human and Bovine Tubercle Bacilli, with Especial Reference to the Milk Supply."

Dr. Frederick Randolph Bailey has tendered to the trustees of Columbia University his resignation as Adjunct Professor of Histology and Embryology in the College of Physicians and Surgeons, New York, to take effect at the end of the present academic year.

Removals.—Dr. T. Wood Clarke has removed to 96 Park avenue; Dr. Frederic J. Leviseur to 680 Madison avenue; and Dr. Alfred E. M. Purdy to 449 Park avenue.

Alumni Association of the New York Lying-In Hospital.—The first annual dinner of this Association will be held on Tuesday, May 11, at 8 P.M. at the Harvard Club, 27 West Forty-fourth street.

Oklahoma Medical Board.—The Oklahoma State Board of Medical Examiners recently adopted a resolution to the effect that no more licenses to practise be issued to physicians suffering from tuberculosis. It was stated that the influx of consumptive physicians from the East was already sufficiently large to cause concern, and it was felt that such action would be for the best interests of the State and the patient.

The South Carolina Medical Association, which was in session at Charleston from April 19 to 22, elected the following officers for the ensuing year: *President*, Dr. John L. Dawson, Charleston; *Vice-Presidents*, Dr. F. H. McLeod, Florence; Dr. C. M. Rees, Charleston, Dr. A. H. Hayden, Summerville; *Secretary*, Dr. Walter Cheyne, Sumter; *Treasurer*, Dr. C. P. Almar, Charleston. The Society also appointed a committee to consider the erection of a memorial to Dr. J. Marian Sims, who was born in Lancaster County, South Carolina.

The Oklahoma Medical Society.—For the purpose of "investigating by discussions, lectures, etc., all that pertains to the profession," the physicians of Oklahoma City, South Oklahoma, and vicinity, recently organized as the Oklahoma Medical Society, and elected the following officers: *President*, Dr. L. W. Benepe; *Vice-President*, Dr. Delos Walker; *Secretary*, Dr. W. M. Baird; *Treasurer*, Dr. H. C. Way.

The Tolland County (Conn.) Medical Association held its 117th annual meeting at Hartford on April 20. The following officers were elected: *President*, I. P. Fiske of Coventry; *Vice-President*, Cyrus E. Pendleton of Hebron; *Secretary and Treasurer*, Eli P. Flint of Rockville; *Counselor*, Thomas F. Rockwell of Rockville; *Delegate to State Convention*, Fred W. Walsh of Rockville.

The Plymouth District (Mass.) Medical Society held its annual meeting at Brockton on April 21. Officers were elected as follows: *President*, Dr. Fred J. Ripley; *Vice-President*, Dr. Charles S. Millet; *Secretary-Treasurer*, Dr. Alfred C. Smith; *Librarian*, Charles E. Lovell; *Reporter*, Dr. A. C.

Smith; *Commissioner on Trials,* Dr. Jesse H. Averill; *Censors,* Drs. Gilman Osgood, Edwin C. Frost, Charles W. Stodder, Arthur L. Beals, and Joseph Frame; *Councillors,* Drs. A. E. Paine, F. G. Wheatley, Gilman Osgood, Nathaniel K. Noyes; *Orator for* 1910, Dr. Harrison A. Chase.

Obituary Notes.—Dr. Allen Vinton Smith of Canton, Ohio, died on April 10 of heart disease, aged 53 years. Dr. Smith was graduated from the Rush Medical College, Chicago, in 1880. During the Spanish-American War he served as assistant surgeon in the 8th Ohio Infantry. He was a member of the Association of Military Surgeons, visiting surgeon to the Aultman Hospital, and a member of the city council and health officer of Canton.

Dr. George G. Farnandis of Baltimore, Md., died at his home on April 4, aged 80 years. Dr. Farnandis was graduated from the University of Maryland in 1852; from 1856 to 1859 and 1870 to 1875 he was physician to the Baltimore Almshouse; and from 1870 to 1873 he was professor of surgery in Washington University, Baltimore. During the Civil War he served as surgeon in the Confederate Army.

Dr. Henry C. Potter died at his home near Santa Barbara, Cal., on April 3, aged 85 years. He was graduated from the Albany Medical College in 1844, and for a short time was one of the health officers of Utica, N. Y. He later settled in Saginaw, Mich., where he practised for many years.

Dr. Charles Wright Huff of Kalamazoo, Mich., died at his home on March 31, aged 59 years. Dr. Huff was graduated from the medical department of the University of Pennsylvania in 1874, and was a member of the Michigan State Medical Society and of the Kalamazoo Academy of Medicine.

Dr. Ernest F. G. Horst of St. Paul, Minn., died suddenly, on March 26, from an overdose of chloroform, aged 55 years. He was graduated from the medical department of New York University in 1876.

Dr. Perry D. Goldsmith of Toronto died, on April 5, after a short illness, at Belleville, Ont., aged 64 years. Dr. Goldsmith was a graduate of the University of Victoria College of Coburg, Ont., in 1868.

Dr. Louis Stern of San Francisco died in the German Hospital in that city, on April 7, aged 55 years. Dr. Stern was educated in medicine at the University of Würzburg, Germany, from which he graduated in 1878. He was one of the founders of the German Medical Society of San Francisco.

Dr. Frederic B. Mandeville of Newark, N. J., died on April 26, aged 69 years. Dr. Mandeville was graduated from the University of Michigan in 1873. He was a member of the American Institute of Homeopathy and the State Homeopathic Society, physician to St. Mary's Hospital, and consulting physician to the Homeopathic Hospital of Essex County. For several years he served as a member of the Newark Board of Education and of the Department of Health.

Dr. Alfred Quin Donovan of Elizabeth, N. J., died in the Elizabeth General Hospital on April 26, aged 55 years. Dr. Donovan was educated at St. Mary's College, Halifax, and at the Bellevue Hospital Medical College, graduating from the latter in 1882. He was a member of the American Medical Association and the State and County Societies, and visiting surgeon to the Alexian Brothers' Hospital.

Dr. Ezra Mitchell of Lancaster, N. H., died at his home on April 20, aged 67 years. After graduating from the Maine State seminary, he entered the Harvard Medical School, but at the outbreak of the Civil War withdrew to enlist in the Maine Volunteer Infantry. At the close of the war he entered Dartmouth Medical College, from which he was graduated in 1867. A sufferer from the disease himself, he became greatly interested in the study and treatment of tuberculosis, and was largely instrumental in effecting the building of the State sanatorium. He was a member of the Coos County and the New Hampshire Medical Societies, and of the American Medical Association, and from 1882 to 1885 was surgeon-general of the State militia.

Dr. Thomas Worcester Dike of Bath, Me., died, on April 17, at Westboro, Mass., after a long illness, aged 43 years. He was graduated from Bowdoin College in 1886 and from the Maine Medical School in 1890.

Dr. Milton Newberry of Whitemarsh, Pa., died, on April 4, at the age of 80 years. He was graduated from the Medical Department of the University of Pennsylvania in 1855.

Dr. Harry Hill died at Bethlehem, Pa., on April 23, at the age of 30 years, from the result of a self-inflicted wound. He was a graduate of the Medical Department of the University of Pennsylvania.

Dr. Louis E. Taubel died at Philadelphia on April 26. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1885.

Dr. George M. Boyd died at Philadelphia on April 28 at the age of 31 years. He was graduated from the medical department of the University of Pennsylvania.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

FAINTING OR FITS—EPILEPSY—LACTIC FERMENTS OR CHEMICAL PREPARATION OF MILK—FLATULENCE—EXTIRPATION OF LARYNX—A NURSING AND MATERNITY EXHIBITION—OBITUARY.

London, April 16, 1909.

Epilepsy is a malady displaying such a variety of phenomena that no definition can include the long list of its clinical manifestations. I say malady rather than disease, as there are some, among them, I think, Dr. Mercier, who deny that it should be called a disease at all, by which they perhaps mean to assert that we do not know it as a pathological entity. Anyone who has been present when a patient has been seized with—shall I say falling sickness?—of a severe type will admit that many other cases, as described by all observers, can well be grouped with that he has witnessed. But when we consider milder cases and the great number of similar or allied manifestations of the disorder, whether we think of them as functional or organic, we find a long catalogue of symptoms more or less related but almost impossible to classify, a sort of scale at one end marked by violent fits shading off to the other end a mere transient feeling of faintness or giddiness. In his Goulstonian lectures, lately delivered at the Royal College of Physicians, Dr. Alfred E. Russell of St Thomas's Hospital maintained that the difference between a mere faint and an epileptic fit is really one of degree rather than of kind, and he found clinical evidence of this in the suddenness of some faints and in the passing of some of them gradually into fits. According to him, the fundamental factor underlying both fit and faint is cerebral anemia—the difference between them being due to the difference in the rate of development of that anemia. In a faint the cerebral circulation slowly diminishes, with falling blood pressure; in an epileptic fit it suddenly ceases. So on recovery

from a faint the circulation slowly improves; from a fit it returns suddenly. The proclivity to fainting, so marked in some persons, is usually associated with other evidences of cardiac and vasomotor instability, and there is usually some exciting cause. In epilepsy, on the other hand, those evidences of an unstable circulation are not so obvious and exciting causes are seldom to be traced.

While holding that the fit or faint is due to a diminution of the volume of blood passing through the brain, Dr. Russell admitted two important factors of this: (1) Vasodilatation in the splanchnic area; (2) cardiac inhibition. In some cases, he thought, one only might be primarily concerned; in others both were involved. Sudden depression of the normal vascular tone in that area caused rapid accumulation in its capacious bloodvessels; if momentary only a sudden sinking feeling at the epigastrium is felt—common enough on being startled. If it lasts, this sort of aura goes on to a faint. A very sudden shock might cause almost sudden unconsciousness and the lecturer had no doubt sudden vasodilatation might occur. It was difficult to judge how often or to what extent the heart might be affected independent of the change in the splanchnic area. But it seemed probable that direct cardiac inhibition might sometimes occur and the two factors might also act simultaneously. The extreme suddenness with which some faints occur suggests a very transient cardiac inhibition rather than splanchnic dilatation. An isolated attack of unconsciousness, and that, too, with a degree of muscular spasm, is not unknown in a person showing no other tendency to faints or fits. In such cases cardiac inhibition seems the most probable cause. The lecturer quoted cases recorded by Sir W. Gowers, in which repeated faints brought on by external influences, after a time appeared spontaneously and with more sudden onset; in fact, became distinctly epileptic. He attributed these to increased rapidity with which the cerebral circulatory change took place. But Gowers postulates some change in the nerve elements of the brain as underlying the loss of consciousness produced by a sudden diminution in the intracranial pressure. If loss of consciousness thus produced should, by frequent induction, acquire a tendency to spontaneous development, that would constitute minor epilepsy. The lecturer submitted rather that the resistance of the nervous mechanism of the cardiovascular apparatus by frequent repetition was diminished, when the reflex would be easier, the failure of the circulation take place more suddenly, and the loss of consciousness be proportionally more sudden.

The lactic acid ferments have been so much discussed and their use in preparing milk for infant and invalid feeding so freely exploited commercially that the simpler plan of precipitating the calcium from cow's milk is in danger of being forgotten. The dilution of cow's milk and the addition of cream, simple as it seems, is to ignorant mothers a difficult undertaking and to those who cannot procure the cream an impossible one. The bacterial method pressed on one who can afford the several products cannot be called economical. Moreover, recent investigations show that the lactic acid tablets on the market are not always trustworthy. There seems, therefore, plenty of room for the precipitating plan, for which two grains of sodium citrate per ounce was shown by Sir A. Wright to be sufficient. Dr. Poynton adopted this method partially, using one grain to the ounce and combining dilution. But Sir A. Wright is satisfied that undiluted milk treated with two grains gives adequate nutriment, and this method has been employed for some two years at the Paddington Children's Hospital by Dr. Langmead, who reported good results a year ago at the Polyclinic and has confirmed them recently at the Harveian Society. The mother is told to bring the milk to a boil and add a teaspoonful of the solution furnished, which contains the quantity required. The citrate can also be added to the milk in bulk by those who can understand the method and may be trusted to do it. Dr. Langmead has treated about seventy cases in this way, all of them children who were wasting under other methods as tested by weighing. Some were lost sight of, a not uncommon thing with out-patients. Of all others he reports excellent results and concludes that this is the most satisfactory method of infant feeding we possess. It is not a therapeutic measure and of course should not be tried as such. But the simplicity of the preparation makes it available for the most ignorant mothers and the fine flocculent curd produced in digestion is a striking contrast to the tough clots frequently vomited when children are fed on raw cow's milk.

Flatulence is a symptom of so frequent an occurrence and often so distressing that every practitioner has probably been asked to explain how such apparently large quantities of gas rapidly accumulate in the stomach. Dr. Cahill of Dublin lately said at the Academy that fermentation is due to decomposition of carbohydrates and putrefaction to that of fats and proteids, but exception was taken to this view and attention directed to the fact that shock or mental trouble may often bring about sudden accumulation of gas, which can scarcely be accounted for by fermentation or putrefaction. This I can confirm, for I have often seen such attacks come on immediately after food and others when the stomach was empty. In the latter case the swallowing of air might be admissible, but in both the expulsion of gas in very large amounts suggested some further cause. In persons with cardiac lesions the distention of the stomach by gas is not only distressing but dangerous. Sir J. Moore remarked on the connection between cardiac and vascular lesions with flatulence and said people with defective teeth were likely to swallow air with food insufficiently masticated and advised attention to the mouth, as it is practically impossible to disinfect the stomach.

At another meeting of the Academy Mr. R. H. Woods showed a case of extirpation of the larynx with a new apparatus for voice production. The trachea was sutured to the skin and the pharynx cut off from the respiratory tract. To enable his patient to speak Mr. Woods fixed a reed in a tube. By passing it through the nose and dropping it over the soft palate and putting the other end into the trachea the man was able to blow and make the reed vibrate. A valve was used to take in air and when his chest was full he put a finger on the end and the air passed into the tube. The instrument having been inserted, the patient saluted the audience and counted ten.

Mr. Dempsey said this case showed what could be done by laryngectomy when the pharynx was quite cut off from the air passage. Mr. Murphy suggested a smaller tube. Dr. Taylor remarked on the ease with which the operator had closed the pharyngeal tube. In reply Mr. Woods said that he had no trouble in securing a pharyngeal wall, as there was plenty to complete a good tube after the larynx was removed. The tube was small enough to pass through the nose. A smaller one would necessitate a smaller reed and that would lessen the power of the voice.

The second annual exhibition and conference in connection with nursing and midwifery was opened on Wednesday and closes with the week. A good many startling, not to say sensational, statements were made, especially as to the mortality of infancy and maternity. The bare facts are enough without exaggerated comment. The midwives Act was only passed in 1904 and now there are 31,000 women enrolled as qualified to practise midwifery and 8,000 or 9,000 remain unregistered. These last are to be forbidden to continue practice next year unless they pass examinations, but they are mostly very poor and very ignorant and so have little hope of qualifying. The registered ones seem to think the others have no claim to pity from those who have contrived to get on the roll and whose education is often little better than the more unfortunate. General medical practitioners are now loudly lamenting that they have handed over so much of their midwifery work to an inferior class. There are many interesting things in the exhibition where sixty-one firms have stalls, incubators, model crèches. Instruction is also given by lectures and demonstrations on the best way of washing, disinfection, and so on. There is a model nursery fitted up on the plan of that of the Queen of Spain, where a nurse gives advice about wall papers, cots, toys, and whatever goes to constitute a hygienic room for a baby.

Mr. Thomas William Nunn, consulting surgeon to the Middlesex Hospital, died yesterday after a brief illness. Born in 1825, he was educated at King's College, took his M.R.C.S. in 1846, and the Fellowship in 1857. He taught anatomy at King's for a time, but on being elected to the Middlesex surgical staff his life work was henceforth in that institution. His books on "Cancer of the Breast" and on "Cancer Illustrated by Cases" were standard at the time (1899) and he contributed various surgical papers to the societies and journals. He served as a vice-president of the Pathological Society. He at one time held a commission in the militia, and held the volunteer decoration.

Dr. Charles Bell Taylor died on Wednesday, aged eighty, at Nottingham, where he had lived so many years and achieved his great reputation as an ophthalmologist. He studied at Edinburgh and Paris, qualified in 1852, took his M.D. Edin. 1854, F.R.C.S. Edin. 1867, having taken prizes at both institutions. His most important work was done as surgeon to the Nottingham and Midlands Eye Infirmary. His "Clinical Lectures on Eye Diseases" appeared in 1876. His new method of cataract extraction was put forth in the Ophthalmic Review, 1867. He contributed to the *Lancet*, a number of clinical lectures on his specialty between 1885 and 1894.

Mr. C. G. Wheelhouse, consulting surgeon to the Leeds General Infirmary, filled a prominent place in the profession for a considerable time, especially in connection with the British Medical Association, of which he was president of Council at a period when it was subjected to much criticism. He was one of the representatives on the General Medical Council, a position attained through the electioneering maneuvers of the rulers of the association at the time. He took his M.R.C.S. in 1849, L.S.A. in 1850, became F.R.C.S. in 1864, had the gold medal of the association presented to him in 1897. He delivered the address in surgery at the Bath meeting and contributed a few articles to the journals. He served on the Council of the Royal College of Surgeons. McGill University conferred on him the honorary LL.D. and Leeds University the D.Sc.

Mr. Wheelhouse was a man of enormous capacity for work and never spared himself. He was for many years treasurer to a medical charitable society in his county, which conferred great benefits on the profession. As a strong man he never hesitated to carry out the views he held, whatever difficulty or opposition he might meet with. Yet he always held the respect and even affection of colleagues and pupils.

MEDICAL NEWS IN THE DAILY PRESS.

To the EDITOR OF THE MEDICAL RECORD:

SIR:—A daily paper has copied from your account of a meeting of the Medical Society of the County of New York the description of a case of penmanship stuttering which I had reported. If I had known that a matter intended for a strictly medical circle would reach the general public I would not have reported this case.

As the fear of republication in the lay press may deter others from publishing some of their work, I ask you to consider what can be done.

E. W. SCRIPTURE, M.D.

NEW YORK.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 22, 1909.

Intracranial Hemorrhage in the Newborn.—Two cases are reported by J. R. Torbert, who briefly refers to the literature of the subject. He discusses the arrangement of the blood-vessels in the infantile brain, and says that it is doubtless fitted by nature to withstand without shock or injury a degree of molding and manipulation which could not be borne by an adult fully developed and medullated brain. And, moreover, in cases of traumatic edema or of actual hemorrhage the distensibility of the partly membranous skull will accommodate effusions of such extent that were they to take place in an adult skull in proportionate extent, they would rapidly prove fatal. The distensibility of the fontanelle and skull is the salvation of many of the subjects of intracranial hemorrhage in connection with birth, for the symptoms are entirely those of cerebral compression, and later in life there may follow such sequelæ as spastic paraplegia, diplegia, epilepsy, etc. In the author's two (fatal) cases there were no localizing symptoms, and this absence is of very frequent occurrence. Many cases certified as dying from inanition are in reality due to intracranial hemorrhage. In cerebellar hemorrhage the infants are at first quiet and nurse well, but the breathing becomes affected. Hence come on cyanosis, irregular and convulsive respiration, cerebral collateral edema, and general convulsions, with death on the second or third day. Cerebral hemorrhage is generally unilateral, and in addition to the symptoms of compression we have restlessness, crying, refusal of food from the first, coma, irregular respiration and heart action, vasomotor disturbances with definite signs of an unilateral focus as facial paresis, spasm of the extremities with increases of the reflexes of the opposite side. Operation alone will help these cases, and the author refers to Cushing's saving of four out of nine cases. The operation consists in raising a large osteoplastic flap opening the dura and clearing away the extravasated blood with normal saline irrigation. The dura is closed, the flap replaced, and the wound closed without drainage. With proper hemostasis and careful avoidance of exposure, a newborn child stands cranial operations well.

The Luys Urine Separator.—B. S. Barringer offers a second report of forty-one cases. The conclusions reached by the author are thus stated (1) There is a class of cases in which knowledge of the condition of the kidneys is necessary and in which the ureters cannot be catheterized. These cases are those in which (*a*) one or both ureteral openings are obscured by cystitis or (*b*) in which the rapid excretion of pus or blood into the bladder clouds the bladder fluid. These are cases in which the separator is invaluable. (2) In children, the child's model of the separator, 17 F., may be used when ureteral catheterism is impossible because of the large size of the catheterizing instrument. (3) Cystitis forms no barrier to the use of the separator and to obtaining an exact knowledge of the kidney conditions in such cases. The exception to this is when a bacteriological examination is necessary, when catheterization of the ureters is more accurate. (4) Separation is much simpler than ureteral catheterization. (5) In women the pain or discomfort caused by the separator is about the same as that caused by the use of a simple examining cystoscope. In men the pain of separation is slightly more marked. (6) There are certain classes of cases in which the separator cannot be used. They are the following: (*a*) Those in which the bladder capacity is less than 20 c.c.; (*b*) those in which the urethra is not penetrable to the instrument, and (*c*) those in which the base or neck of the bladder is distorted by (*a*) marked prostatic hypertrophy, (*b*) extreme anteversion or antetlexion of the uterus, (*c*) certain uterine tumors, and (*d*) marked cystocele. (7) Slight hemorrhage occurs in some cases resulting from the bladder muscle grasping the instrument too vigorously and causing trauma of the vesical mucous membrane. This is shown by (*a*) small blood clots along the membrane when the separator is withdrawn, and (*b*) slight and equal increase in the fresh red blood cells of both sides. (8) Any inaccuracy of results obtained by the use of the separator is to be attributed to its employment in unsuitable cases or to a failure to recognize traumatic hemorrhage when it occurs, and does not arise from leakage of the urine from one side to the other.

Vaccines in Typhoid.—W. H. Watters and C. A. Eaton report four more cases of typhoid, a mother and three children. All were attacked at the same time from another case in the family. One child was treated in the usual way with baths and medication p. v. n. The other three were treated with vaccines. The charts accompanying the paper show that the two children inoculated did well from the start, and in a few days all the clinical symptoms had disappeared. In the case of the mother, the fall in temperature was less conclusive as to the value of vaccine treatment, but the general clinical course went on just as satisfactorily as with the children until a period in which after a severe nervous shock, the temperature rose to 105° and was not lowered by the inoculation then given. A hemorrhage then occurred, but without any serious physical indications of trouble. Thence convalescence was slow but steady. The authors do not attempt to dictate deductions, but say that from their personal experience with about forty cases, it seems probable that the early administration of typhoid vaccines will often materially shorten the disease and that even if the temperature is uninfluenced, the case runs a very mild course. In a hospital series of 77 cases, 31 were treated with vaccines with a mortality of 3.2 per cent., while the mortality of those not receiving vaccines was 123 per cent

New York Medical Journal, April 24, 1909

Acute Suppurative (Phlegmonous) Ethmoiditis in Children, Ending in Death.—F. Krauss reports two personal cases and reviews recent literature on the subject. His patients were girls of nine and thirteen years respectively, the case histories presenting nothing unusual. The author has an increasing conviction that acute suppurative ethmoiditis causing orbital and cerebral symptoms is more common than is currently supposed and that in the young this lesion is often rapidly fatal. The indications for operative intervention in acute conditions are sudden increase of temperature, delirium at night, tumor formation in the inner wall of the orbit, and the slightest exophthalmos. Operation should not be delayed too long. The same general

rule holds true here as in appendicitis—early operation being harmless, while late operation is generally useless. When there is bilateral exophthalmos, operation is generally useless, as the lesion has probably extended through the cavernous and circular sinuses, causing a general toxemia and pyemia or a fatal lesion of the brain.

Spirochæta Lymphatica.—The results of further studies of this organism are reported by Proescher, who details his experience in experimental inoculation of monkeys and rats. According to the present conception of the disease, the changes in the lymph glands may be classified as follows: (1) The acute and chronic lymphadenitis (including lues and tuberculosis); (2) leuchemic and aleuchemic lymphomata (pseudoleuchemia, granulomatous and hyperplastic forms with or without blood changes). The pathological anatomy in the leuchemic and aleuchemic varieties is practically the same and consists either of a pure lymphatic hyperplasia or, as is occasionally seen in one form of pseudoleuchemia, a granulomatous hyperplasia. (3) Primary sarcoma of the lymph glands (excluding sarcoma which develops from the connective tissue stroma), or lymphosarcoma, which preserves more or less the character of the lymphatic tissue and which might be better named lymphocytoma (Ribbert) or granulolymphocytoma, or malignant granuloma (Benda), also the leucosarcoma described by Sternberg and accompanied by a characteristic blood picture, and finally the chloroma which resembles morphologically the lymphosarcoma but differs in the production of a greenish coloring matter. The author does not believe that attenuated tubercle bacilli can produce a lymphomatosis. The infection is more likely a secondary one.

The Significance of High Blood-Pressure in Life Insurance Examinations.—The use of the sphygmomanometer is commended by R. Grace, who discusses the use of the instrument and the significance of its records. The physical factors of arteriosclerosis are considered from their clinical side. The high readings in a hypertonic contracted vessel possibly sclerosed are due to the thickening of the vessel wall and the narrowing of its lumen. Substances in the circulation may act directly on the vessel wall without the medium of the nervous system causing contraction of the muscular coat. The source of these substances that even in small quantities cause arterial contraction and raising of the blood pressure is through the alimentary tract, particularly intestinal. As a result of these disorders of alimentation, toxic substances are developed and absorbed into the blood which act directly on the vessel wall, causing this dangerous hypertonicity which should be an element of concern to the examiner. This hypertonicity that exists either in the sclerosed vessel or the sclerosed atheromatous vessel or in the healthy vessel and gives us the high reading, can be relieved by proper hygiene, diet, etc., and we may remove this so-called high blood pressure and find an applicant to be a risk of the first class rather than one to be refused on account of dangerous disease. The very high readings that are obtained in cases of interstitial nephritis are caused by the pathological changes in the arteries that are invariably met with in that disease, and cannot be materially effected by treatment; but high readings do not necessarily mean either arterial or kidney disease; we must recognize this hypertonic contraction of the vessels as a factor in high sphygmomanometer readings and depend greatly upon the microscopical findings of the urinary analysis for our diagnosis of kidney affections.

Journal of the American Medical Association, April 24, 1909.

Oatmeal Diet in Diabetes.—A. C. Croftan gives the following clinical classification of the disease, which he finds convenient and useful. Type 1: In these cases the sugar disappears within two or three days after complete withdrawal of carbohydrates. The patients still possess a small tolerance. The clinical significance of the type is according to the age. In young patients the outlook is always more serious and they almost invariably develop the severe type unless the greatest care is used. In older patients, in whom it is usually associated with obesity, gouty manifestations, or arteriosclerosis, the outlook is specially favorable so far as their developing the severe type of diabetes is concerned. Type 2: The sugar cannot be made to disappear until the patient has been on a carbohydrate diet for two or three weeks. It includes three groups. In group 1, with the gradual reduction and final disappearance of the glycosuria, there is a general improvement in condition, increased weight, and reduction of the acetone bodies of the urine to the normal. In group 2 there is an initial loss of weight, general malaise and weakness, and increase of the acetone bodies. With the complete disappearance of the sugar, however, the weight again increases, sense of well-being improves, and the acetone bodies become normal. In group 3 there is loss of weight and strength and an alarming degree of acidosis, with corresponding larger excretion of acetone bodies. Such patients often develop digestive disorders and in bad cases relapse into coma if the oatmeal diet is persisted in. Type 3: The sugar does not disappear from the urine even with a carbohydrate free diet given for many weeks, and, while reduction of the food albumins often causes a disappearance of sugar, it promptly reappears with the use of the normal protein ration. These patients usually excrete large quantities of acetone and its congeners and rapidly emaciate. The "von Noorden oatmeal cure" is worse than useless in mild cases of the first type occurring in adults or elderly people. These patients respond to it by increased glycosuria and often by severe digestive disturbances. It is also harmful in groups 1 and 2 of the second type of diabetes and may do irremediable damage. In juvenile cases of Type 1 and of Type 3 this method is distinctly useful and brilliant results are occasionally observed. Adults, in cases of the very severe type, do not respond so well, but with certain precautions no harm can result from a trial, and, in view of the general inefficacy of ordinary methods of treatment in diabetes, it should at least be tried. While in juvenile patients no time should be lost, however, in adults oatmeal feeding should be considered a last resort after other methods have failed. Croftan does not advise the unpalatable fatty porridge or soup of von Noorden, but says that there are many more agreeable ways of employing it. In children the gruel treatment is probably the simplest and they object to it least. In patients reacting favorably to this method the resumption of a general diet must be very gradual and oatmeal should be exclusively used for many months. In his experience it is especially precarious to mix carbohydrates after an oatmeal course. Animal proteids should always be resumed with care. It is a good rule in beginning this diet, and a safe one, to give up the oatmeal diet if no benefit is seen after five days' trial. As a precaution against acidosis from two to four teaspoonfuls a day of sodium bicarbonate, either alone or mixed with equal parts of magnesia usta, should be given throughout the oatmeal treatment. The most brilliant results are obtained in children, especially if the oatmeal cure is administered as soon as possible after the diabetes is discovered. In cases of longer duration than two or three weeks children under fifteen years of age do not fare so well. In adolescents and adults the results have been on the whole favorable rather than otherwise. Since the mild cases of Type 1 and certain cases of Type 2 are excluded as altogether unsuitable from this summary, there remain only a limited number of severe, usually old, cases of diabetes to be considered. In no case has he seen a complete cure so that a general diet could be resumed, but there was often a marked improvement, and even in recent cases of diabetes in adults or adolescents he has not seen any such brilliant results as are occasionally observed in children.

Indurative Headache.—N. S. Yawger describes a form of headache which has received little mention in the text-books by American physicians, but has been recognized for years and studied abroad, notably by the Swedes and Germans. Edinger, indeed, makes the statement that, though indurative headache is almost unknown, it is probably the most common form of the disease. In seeking the cause of the condition we find that at the insertions, or within the bodies of the muscles of the head and neck, there appears a deposition which comes and goes at first, and later becomes chronic, and which gives rise to stimulation or irritation of the sensory nerve fibers, thereby causing pain. Given the chronic condition, a paroxysm may be brought on by emotional disturbance, exposure to draughts, atmospheric changes, etc. These deposits actually exist and give rise to a chronic myositis at the points of their lodgings. They are found present in three stages: (1) A soft, yielding swelling; (2) a slightly elastic resistance to the touch, as if some organization had occurred; (3) a hard, inelastic induration with a cartilaginous feeling. The older these deposits the firmer they are and the more resistance they offer to treatment. They occur sometimes also in other parts of the body and may give rise to diagnosis of sciatica and even appendicitis. There is no

fever or redness with them and their favorite location is, as stated, in the muscles of the head and neck. The symptoms are of two kinds, those of the chronic condition and those of the paroxysm. The pains develop gradually, but become more constant and severe the longer the disease continues. Local pressure often affords relief, but if an actual neuritis exists the suffering will be intensified. The patients are susceptible to colds and are liable to mental depression and there may be other symptoms of disturbed nutrition in various parts of the body, gastrointestinal disturbance, myalgia, hypersensitiveness of the teeth, etc. Many of the cases are neurasthenic and it is possible that an excess of uric acid or some other substance is concerned in their production. Before an attack of headache the enlargements become swollen and sensitive, and the pain follows usually over their sites. It may be mild or severe and may radiate. The examination should be made by forcible flexions and twistings of the neck and pressure over all portions of the scalp wherever nodules or indurations are discovered. The diagnosis is made from meningitis by the lack of the indurations and hypersensitiveness and the presence of fever. In migraine there is often a sensitive aura and painful areas are absent, while vomiting and nausea are present. The two conditions may coexist, however, and neuralgia and neuritis may result from these thickenings. Under efficient treatment in from four to three months these enlargements can usually be removed. There are a few cases, however, of such cartilaginous induration that only improvement can be expected. Persons who have tendency to this condition should take active exercise in the open air, drink water freely between meals and avoid over-fatigue and emotional excitement. If relationship with uric acid is proved the diet should be low in purin percentage. It should be nutritious, easily assimilated, and not too abundant. Alkaline waters are useful, tea and coffee should be used only sparingly, and alcoholic beverages should be avoided. Internal medication is of little use unless a tonic is indicated, but potassium iodid may give some relief in advanced cases. For a severe acute attack a brisk purgative, a warm bath, hot dry applications to the affected part, and the salicylates are advised. The removal of the thickenings will take from one to three months, and the effective measures are, in the order of their effectiveness, massage, vibration, and galvanism. Vibration by the electric vibrator is conducive to absorption, but should be avoided in patients with arteriosclerosis. Massage, however, is the most effective method of removing these deposits. At first it is painful, but after a few treatments the sensitiveness disappears. In all cases the bowels should be kept active, not merely open but emptied daily, and this can be done by use of laxative mineral waters. The treatment is complete when the swelling and pain have disappeared.

The Blindness of Hysteria.—H. Gradle says that the real importance of psychic influences on the eye is more apparent in the oculist's office than in the neurological clinic. He reports a case of double-sided complete blindness and one of unilateral blindness, in neither of which was there occasion to suspect simulation. He has seen other cases of unilateral amblyopia, so-claimed, in which, however, he suspected malingering. Of much greater clinical significance are the cases that he has observed of the failures of good vision in persons not suffering from hysterical manifestations; at least, not at the time. In his observations of these cases he found no contraction of the visual fields nor marked changes in color vision and his suspicions as to their hysterical nature were based on the lack of other explanation and the emotional instability of the patient, as well as the fugitive character of the symptoms. Two cases of this class are reported. He has also observed hysterical exaggeration of congenital amblyopia in a child, and also reports two cases of children which are samples of others in his observation, in which the condition was, in his opinion, hysterical or imaginary. Youngsters with vivid imagination are apt to consider disturbances created by their fancy as real, and these cases are difficult sometimes to distinguish from real hysterical blindness.

The Lancet, April 17, 1909.

The Rôle of the Saliva in the Transmission of Tuberculosis.—N. Nield and E. V. Dunkley have examined 50 patients with pulmonary tubercle, in whose sputa the bacillus was demonstrable. Inoculations from saliva taken from the surface of the tongue, on to albuminised slides revealed tubercle bacilli in 29. Many patients engaged in mechanical pursuits are accustomed to spit on the hands before grasping the tools of their trade, and may thus transmit tuberculosis to subsequent users of those implements. Seamstresses moisten the threads with saliva before threading their needles, and knot the terminal end in the same way. They may thus be unwittingly conveyers of the disease to those who wear the products of their needle work. Envelopes which have been sealed by moistening with the saliva of tuberculous patients have been examined and found to contain bacilli in the gum thus imprisoned. The authors refer to several authentic instances in which the saliva has been the medium of inoculation. The method common among the poor of cleaning children's faces with the handkerchief moistened with the mother's saliva, and of moistening the nipple before the child is put to the breast, are also possible methods of contagion. All tuberculous persons should be forbidden to moisten the fingers with saliva for any purpose whatever, and the same prohibition should be encouraged in the healthy, for example's sake, let alone any other reason.

A Case of Vascular Degeneration; A Study in Arrhythmia.—A. M. Gossage presents copies of pulse tracings taken from a man of 68 years, evidently suffering from fibrosis of the heart, associated with coronary atheroma. In consequence of this the contractile force of the muscle was deficient, leading to pulsus alternans and attacks of angina pectoris. The fibrosis had probably invaded the auriculo-ventricular bundle, causing an increased irritability and hence numerous extrasystoles arising in the primitive tissue, of which the bundle is composed. In the cardiac cycle it was noted that there were frequent intermissions, that at times the rate of the pulse was infrequent, and at other times the frequency was normal. The apex beat was one-half an inch outside the normal position. The first sound was shorter than normal. Not infrequently the extra systole appeared in the sequence of a premature feeble systolic sound, followed by a long pause. Besides there were numerous pauses or intermissions, during which no feeble sound was heard. It was considered that owing to insufficient blood supply to the cardiac walls the fibrosis had come on. The anginoid pain was partly constant and partly paroxysmal in character, being brought on by exertion. It was greatly relieved by nitroglycerin.

Disease of the Hip Joint Due to Streptococcal Invasion with Secondary Manifestations in Other Parts.—W. O. Beddard's patient was a healthy looking boy of 12 years, complaining of pain on the outer side of the right thigh. The hip joint was held fixed and any attempt to move the joint or extend the knee aggravated the thigh pain. These symptoms gradually subsided and later returned with fever and evidences of local swelling about the hip joint. The *x*-ray picture was negative at this time. Thence for a period of 170 days from the time of the initial thigh pain, the symptoms grew better and more gradually leading to a positive diagnosis of joint trouble, which was finally confirmed by a skiagram which showed a disappearance of the upper lip of the acetabelum and an upward displacement of the femur. The latter bone was intact but rarified, not apparently in the way typical of caries. The condition was decided to be non-tuberculous. The hip was excised in the usual way and the wound healed by first intention. Two weeks later the right knee was inflamed, but later gradually improved. At the end of a year after operating the boy could walk with a stick, but the leg involved was shortened one inch. The right knee was somewhat enlarged, but could be almost completely flexed. The author believes that if a positive diagnosis could have been made early in the disease the vaccine treatment would have afforded more relief and have materially shortened the period of treatment. Examination of the material removed from the hip joint revealed a Gram-positive coccus, showing on solid media a growth of staphylococcus, and in fluids the characters of streptococcus. It could not be identified with any known species of either.

Anterior Metatarsalgia.—A. Mackenzie Forbes summarizes the treatment of "Martoris toe" as follows. (1) Protection against lateral pressure, and (2) the elevation or support of a depressed arch with suitable protection of the plantar surfaces of the heads of the bones. The elevation of the fore part of the foot is also of importance. Operative treatment as suggested by Marton should be applied only in those chronic and resistant cases where conservative treatment has failed. In certain cases characterized by great spasm of the extensors the transference of the attachment of these tendons to the dorsal aspect of the heads of the metatarsals may be considered.—*Montreal Medical Journal.*

Book Reviews.

Variations of the Bones of the Hands and Feet. A Clinical Atlas. By Thomas Dwight, M.D., LL.D., Parkman Professor of Anatomy at the Harvard Medical School. Philadelphia and London: J. B. Lippincott Co.

Now that the *x*-ray is in such common use in the diagnosis of fractures and other injuries, it is of the utmost importance that the surgeon should be acquainted with the variations that may occur in the bones. The present volume deals with such variations in the hands and feet, and a knowledge of some of these may prevent a mistaken diagnosis of fracture. The bulk of the book is an atlas, chiefly of skiagraphs; but there is a most valuable prefatory chapter dealing with the variations, additional bones, fusion of bones, and variations of relations that may be found in hand or foot. The work is practical rather than scientific, and is intended for the general practitioner, but it will prove useful also to the anatomist, the surgeon, the *x*-ray worker, and every one who has occasion to interpret a skiagraph.

Military Hygiene. A Manual of Sanitation for Soldiers. By R. H. Firth, Lieut-Col. Royal Army Medical Corps, Officer in Charge School of Army Sanitation, Aldershot; Formerly Professor of Military Hygiene in the Royal Army Medical College, London. London: J. & A. Churchill; Philadelphia: P. Blakiston's Son & Co., 1908.

This book is written for the layman—the soldier—and both in subject matter and in language it is a model of what such a book should be. It begins by pointing out to what extent disease has prevailed and contributed to military inefficiency in the past and how much it prevails in the army, even now. Then the causes of disease are considered, and it is made clear that all preventible diseases come from without. The physical training of recruits is inculcated on the lines of physiological teaching in place of the old rule-of-thumb methods; and the housing, feeding, clothing, and general equipment of the soldier are all elaborated. The application of hygienic laws and principles to the circumstances of the march, the bivouac, and the camp is then considered, and the whole is admirably treated in a most readable pocket volume of three hundred pages.

A Text Book of General Bacteriology. By Edwin O. Jordan, Ph.D., Professor of Bacteriology in the University of Chicago, and in the Rush Medical College. Fully Illustrated. Philadelphia and London: W. B. Saunders Co., 1908.

This is one of the newest works on bacteriology, and it is written from the viewpoint of one who believes that bacteriology should be studied in every scientific course. Hence the present volume is not written especially for the medical student, any more than for students interested in agriculture, sanitary engineering, or technology. The book is a good one: it covers the ground quite thoroughly, and the subject matter is well arranged and well written. There are numerous bibliographical references which add to the value of the work. For the general scientific student this volume will certainly prove of value; but the medical student, with his overcrowded curriculum, had better select one of the numerous works written specially for him by one who knows his special requirements and caters to them alone. For those who are not beginners, or who are anxious to review the subject from a broader basis than is generally possible for the medical student, this book is all that can be desired, and will prove a welcome addition to any library and to every laboratory.

Maladies des Reins. Par E. Jeanselme, Professeur Agrégé à la Faculté de Médecine de Paris, Médecin de l'Hôpital Broca. A. Chauffard, Professeur Agrégé à la Faculté de Médecine de Paris, Médecin de l'Hôpital Cochin, Membre de l'Académie de Médecine. P. Emile Weil, Ancien Interne des Hôpitaux de Paris. L. Laederich, Ancien Interne des Hôspitaux de Paris. Avec 75 Figures Intercalées dans le Texte. Paris: Librairie J. B. Baillière et Fils, 1908.

This is the twenty-first fascicle in Brouardel and Gilbert's "Nouveau Traité de Médecine et de Thérapeutique," published under the direction of Prof. A. Gilbert and Prof. L. Thoinot, and, like its predecessors, the work has been done by specially selected authors, who are authorities on their respective subjects. The first part of the work deals with physiological facts concerning secretion and excretion of the urine, the physical and chemical characteristics, along with the microscopical and biological peculiarities of the kidneys' secretion.

Following this, the subjects of anuria, polyuria, indicanuria, hematuria, hemoglobinuria, chyluria, albuminuria, and kindred abnormalities are considered, along with the microscopic findings. The clinical deductions are then treated separately by the authors of these foregoing parts, Jeanselme and Weil. The diseases of the kidneys, including nephritis, congestions, tuberculosis, abscess, perinephritis, parasitic diseases, cancer, calculus, nephroptosis, and hydronephrosis are thoroughly described by Chauffard and Laederich. The great bulk of the book deals with nephritis and in a most satisfactory manner. The clinical varieties are well divided, the theories, for instance, of edema and arterial tension, are given with due judgment and conservatism, and brief but sound methods of treatment are advised. A few plates serve to elucidate the text, although the clear descriptions, concise and told in an interesting manner, are vivid enough to make an unillustrated edition well worth reading.

Diseases of the Nervous System. For the General Practitioner and Student. By Alfred Gordon, A.M., M.D. (Paris), Associate in Nervous and Mental Diseases, Jefferson Medical College; Neurologist to Mount Sinai Hospital, to Northwestern General Hospital, and to the Douglass Memorial Hospital; Late Examiner of the Insane, Philadelphia General Hospital; Member of the American Neurological Association; Fellow of the College of Physicians of Philadelphia, etc. With 136 Illustrations. Philadelphia: P. Blakiston's Son & Co., 1908.

The author lays considerable stress, in his preface, on the necessities of clearness and practicability as underlying qualities for a text book or treatise on the difficult subject of neurology, especially when such a book is written expressly for the student and general practitioner. We expected, therefore, in perusing the book, to find a directness and simplicity of style and a logical sequence in the discussion of subjects. We regret that in these respects we were a little disappointed. The plan of the book is to give first the anatomy and physiology of the central nervous system. Next, methods of examination for diagnosis. Then follow consecutively diseases of the brain, diseases of the spinal cord, functional nervous diseases, diseases of the sympathetic nervous system, and, finally, nervous symptoms produced by intoxications. The anatomical descriptions are far from clear, and would be more practical if simplified and accompanied by hand-in-hand statements of function. Every student of neurology knows how difficult it is to find clear and comprehensive descriptions of the physiological functions of the various tracts and centers. The beginner, we fear, will be hopelessly muddled by this part of the book. The chapter on "Examination for Nervous Diseases" is also incomplete, even for the use of the general practitioner. The author's classification of nervous diseases and his arrangement for description are not especially scientific. There are many good illustrations. The book offers a striking example of the well recognized fact that the possessor of knowledge is not always able to impart it. Those who know of the author's profound knowledge, his earnestness and enthusiasm, will regret that those gifts were not joined with a talent for lucid expression, so as to make the rich stores of learning which the work contains readily accessible to the reader.

Vorlesungen über die mechanische und psychische Behandlung der Tuberkulösen besonders in Heilstätten. Von Dr. Georg Liebe, Leiter und Inhaber der Heilanstalt Waldhof Elgershausen. München. J. F. Lehmann's Verlag, 1909.

These fourteen lectures make up the first volume of a proposed series dealing with the mechanical and psychic aspects of tuberculosis. The author believes that patients should be given a moderate amount of work to do, which shall keep them in the open air much of the time. For this he recommends landscape gardening and farming on a small scale as quite suitable. Indoor exercise can be had to advantage in a gymnasium under control of a physician skilled in such activities, or in the patient's own room, if need be. Liebe believes that "most people breathe badly," and hence favor the propagation of lung diseases. Deep breathing he regards as an enemy to the bacillus tuberculosis, and also as an adjuvant in constitutional tissue building. As recreations, he recommends books, pictures, music, singing, declamation, writing, card playing, and nature study. A suitable translation of this book into English would be of help to many patients and of interest to the physician.

Society Reports.

AMERICAN SOCIETY OF TROPICAL MEDICINE.

Sixth Annual Meeting, Held at Washington, D. C., Saturday, April 10, 1909.

JAMES M. ANDERS, M.D., PRESIDENT, IN THE CHAIR.

THE President of the Society, Dr. JAMES M. ANDERS of Philadelphia, read an address entitled, "A Review of the Year's Progress in Tropical Medicine."

The Secretary, Dr. JOHN M. SWAN of Philadelphia, read his report, in the course of which he gave a biographical sketch of Dr. Azel Ames, a member of the society who had died during the year.

Malaria, with Especial Reference to What Is Not Malarial Fever.—Dr. JOHN PELHAM BATES of Nashville, Tenn., in an exhaustive paper on this subject, drew the following conclusions: (1) Malaria is an extremely simple disease, unless complications are present. In true malaria, with the patient at perfect rest, quinine will control all symptoms within five days; if not, death will be so prompt that there will be no time to hesitate over the diagnosis. It is important to remember the large number of infections that may be present along with an acute malarial infection. Lack of knowledge of this fact accounts for the confusion in our ideas with regard to the course of malaria and its nonamenability, in exceptional instances, to treatment. Finding malarial parasites in the blood is not the end, but the beginning of the diagnosis. When quinine fails to have a marked effect upon the fever within forty-eight to sixty hours, although parasites may be present, there is some complication; and when the fever is once reduced by quinine and there is again a rise of fever, the second rise is not due to malarial infection, but to an intercurrent infection manifesting itself late in the attack. In the presence of a marked leucocytosis, the idea of malarial infection should be abandoned and search should be made for the real cause.

Report of a Case of Quartan and One of Estivo-autumnal Malaria.—Dr. JOHN M. SWAN of Philadelphia reported these cases. The quartan infection was accidentally discovered in a patient admitted to the hospital for nephritis. The man had recently landed from Jamaica. His blood was studied and found to contain a single generation of quartan parasites. He had no chill, but his temperature was 99.4° at 8 A.M. on Oct. 9. Seventy-two hours later the temperature registrated 100.4°, without chill; at the next seventy-two hour period there was a chill, the temperature reaching 101.4°. The nephritis was independent of the malarial infection. The return of the dropsy, with chest pain, chills, cough, and blood-tinged expectoration was unaccompanied by the recurrence of the sporulating parasites in the peripheral blood, and examination of bone marrow after death failed to show malarial pigmentation.

The second patient, a male, was admitted to the Polyclinic Hospital, complaining of hiccough. He had an intermittent temperature. No suspicion of malarial infection was entertained, but at autopsy the very large spleen suggested the nature of the disturbance, and smears made from the expressed spleen pulp showed a large number of pigmented macrophages and a fair number of deformed and partly degenerated parasites. The lung seemed to be affected by hypostatic congestion. On histological examination a pneumonic consolidation was seen. The exudate was not that of a true pneumococcus infection.

A Study of the Leucocytes in Tropical Malarial Infections.—Dr. PAUL T. TALBOT of New Orleans referred to a group of malarial cases that suggested to him the necessity for careful study. The condition had been termed "tropical anemia." The patients all gave a history of ague. There was a relative white blood count, which showed an increase of the small lymphocytes, with an erratic form of plasmodium. A great amount of physical depression existed. Every blood disease had its own picture, and it was possible that there was some change in the leucocytes, not yet determined, that represented a certain organism or toxin. Ordinarily the leucocyte count was a valuable aid in the diagnosis; these cases, however, showed the relative increase in the lymphocytes in the small rather than in the large varieties. Sometimes the plasmodium was that of an estivoautumnal form. The author concluded, therefore, that he was dealing with a different toxin, produced by a different parasite.

Dr. W. S. THAYER of Baltimore said that he was surprised that Dr. Bates should have stated that malarial parasites were not found in any greater number in the internal organs than in the peripheral blood. Not infrequently a moderate number of parasites were found in the peripheral circulation and an enormous number in the internal organs. There were occasional cases of malarial fever in which no parasites could be found in the peripheral circulation, even with the most careful staining. Dr. Thayer had also seen cases in which tuberculosis exactly simulated malaria, but in which the blood showed no parasites. He had likewise encountered trichiniasis resembling malaria most markedly. The paroxysms were like those of estivoautumnal infection.

Dr. C. G. BASS of New Orleans reported a case similar to Dr. Swan's. After the man had been in the ward three or four days twenty grains of quinine were given to him by mistake. It was immediately stopped, when discovered. The plasmodia were absent the next day, and from that on, until a month and a half later, he had had no more parasites. He had previously shown three crops of parasites. He died two months later, and at postmortem tuberculous peritonitis was disclosed. Dr. Bass then referred to a second case of quartan malaria, in which the patient had died within a short time after treatment, and showed markedly few evidences of malaria at the autopsy.

Dr. THAYER mentioned a case of the obstinate type of quartan malaria in a man who had consulted Dr. Osler on account of recurrent chills. Dr. Osler did not think it was one of malaria, but Dr. Thayer examined the blood and found quartan parasites.

Dr. BASS cited two other cases of quartan malaria. On admission, one patient showed an enlarged spleen and a triple infection, with three crops. At the end of three days the disease had yielded to quinine, but he was kept in the ward ten days more. The pathologist at the Charity Hospital had thought he could recognize a different type of plasmodium in the patients coming from Honduras, and had named it the Honduran malarial parasite.

Dr. GEORGE DOCK of New Orleans said that the old English idea of the greater severity and obstinacy of quartan malaria did not always hold good. He then referred to the enormous number of parasites that had been found in Dr. Bass's second case, yet the patient that died had had practically no symptoms. There was also a very decided estivoautumnal infection, a crescent having been found later on. In regard to the distribution of the parasites in the blood, he said that the circulation did not go on as in a series of tubes without any outlet; he then spoke of a patient in whom he was unable to find parasites in the circulating blood, yet found quantities on puncturing the spleen. Dr. Dock agreed with Dr. Bates that most cases of malaria could be checked in forty-eight hours, holding Dr. Osler's limit of five days to be too long. He thought that the microscope should be used, and, if necessary, the spleen punctured.

Dr. O. T. LOGAN of Chingteh, China, referred to the patient mentioned by Dr. Bass who got well. He thought the recovery explained by the fact that our forefathers got well before the discovery of quinine. In China several

persons had come under his observation who did not believe in taking medicine. By simply remaining in bed they eventually got well.

Dr. HENRY SKINNER alluded to the facts mentioned by the previous speakers in regard to the Honduran parasite, and said that the formation of a distinct species or a geographical race was to be expected when this amount of distribution was found.

Dr. W. P. CHAMBERLAIN of Jackson Barracks, La., said that in studying malaria he had found four patients who resisted the administration of quinine by mouth for four days, the rest yielding promptly to treatment.

Schistosomiasis (Japonicum), with Especial Reference to Observations in Hunan Province, China.—Dr. O. T. LOGAN of Chingteh, China, said that the existence of this disease seemed to be connected with wet farming. Diagnosis was usually easy, though it might be necessary to make examinations on several days before the characteristic ova were found in the stools. It was believed that the infection took place through the skin in persons who waded in stagnant water. The prognosis was bad in heavy infections; and even light infections lowered the vital resistance and rendered the patient more liable to concurrent infections.

The Prevalence and Importance of Uncinariasis Among Apparently Healthy Southern-Bred White Men in the United States Army.—Major WESTON P. CHAMBERLIN said that uncinariasis was very common among soldiers of less than three years' service. Of one hundred serving in their first enlistment, sixty were infected. It was believed that uncinariasis in childhood was the cause of the poor development so common among Southern-bred recruits. Those who led a farm life were frequently infected with hookworms, as most persons on farms habitually went barefooted in childhood; more than half of these had, probably, suffered from ground itch during their youth.

Mild Uncinaria Infections.—Dr. CHARLES C. BASS of New Orleans called attention to the fact that the negro presented fewer symptoms, even when laboring among these parasites. He then described in detail the method of obtaining the ova by the means of the centrifuge.

Dr. THAYER of Baltimore opened the discussion on the two preceding papers by saying that it would be of great interest to study the stools in *Strongylus stercoralis* infection by the method described by Dr. Bass, in order to determine the relative measurements of these eggs and those of uncinaria. The eggs of the former were very rarely found in the stools; and when they were found, were so like those of uncinaria that there was sometimes a question as to which they were.

Dr. SWAN mentioned a patient who had recently come under his observation. He had had, at periods of four weeks, epileptiform attacks of considerable severity, and upon examination of the blood an eosinophilia of 15 per cent. was found. A pretty large flagellate infection was discovered by examining the stools. After appropriate treatment for two months there was no return of the convulsions, and, in spite of repeated examinations of the stools, Dr. Swan failed to discover any uncinaria eggs.

Dr. JOSEPH SILER of Port Jay, N. Y., thought the question of prophylaxis of uncinariasis ought to have more attention, as the South would never get rid of the hookworm unless the question was taken up by the Government. The fact that nearly all the children of the South were infected made him conclude that if that section could get rid of the hookworm a great deal would be done for humanity.

Dr. CHAMBERLAIN closed the discussion by saying that his cases were widely distributed, every State in the South being represented, even as far north as Maryland.

Dr. BASS agreed that ridding the South of this infection was of very great importance. He thought, however, that the question must be one of education, rather than of legislation; as it would be impossible to force the layman by law to observe such sanitary measures as would be necessary to prevent this disease.

The Relation of House-Flies to the Spread of Disease.—Dr. HENRY SKINNER of Philadelphia read this paper. This insect, he said, oviposited in horse manure, decayed vegetable matter and meat, cow dung, fowl droppings, and human excrement; but the vast majority of house flies were bred in horse manure. The house fly as a carrier of typhoid fever was very dangerous. Wherever flies could gain access to material containing the *Bacillus typhosus* they were almost certain to carry it to food. They had long been suspected of being agents in the dissemination of cholera and other intestinal diseases. So far as was known, however, the house fly was only the mechanical conveyor of bacteria, and was not the host of any known animal disease-producing organism similar to the protozoan organism that caused malaria. If the insect could be prevented from depositing its eggs in horse manure the fly as a pest would soon be a thing of the past. The manure should be rammed into barrels that could be tightly covered.

Dr. P. M. ASHBURN, U. S. Army, opened the discussion on Dr. Skinner's paper by saying that he had, some time ago, prepared some slides covered with some serum, when he discovered a fly busy in eating some of the serum. He caught the fly, and found in its proboscis two larval enoatodes that were indistinguishable from strongyloides. He thought that in this way the fly might be a carrier of intestinal parasites—possibly of uncinaria. He also said that in the Philippines flies were much less common than in the United States in the summer time.

Dr. LOGAN said that in China the blue-bottle fly was more common than the house fly.

Dr. GEORGE DOCK said that the only way to get rid of house flies was to observe absolute cleanliness; if a soup-plate containing sugar water and a 10 per cent. formalin solution was placed in the room it would be found pretty effective in keeping the flies down. The odor could not be perceived, but the flies were absolutely destroyed.

Mr. H. L. VIERECK of Washington, D. C., said that at the laboratory in Harrisburg, Pa., while specimens were being immersed in 4 per cent. formaldehyde it was found that the flies were attracted by the formaldehyde solution, which they sucked up; and that they died in great numbers.

Dr. SKINNER, closing the discussion, said that there were numerous records of places in the tropics in which house flies were very abundant. He considered that further information would be very valuable, as the pest is one distributed pretty well all over the world, and especially prevalent in Southern Europe.

The Etiology of Pellagra.—C. H. LAVINDER of the U. S. Health and Marine Hospital Service, Washington, D. C., read this paper. After an exhaustive review of the subject, the following conclusions were drawn: The cause of Pellagra is essentially unknown. The idea, in one form or another, that there is an etiological relation between pellagra and the use of maize as a food is not likely to be abandoned, as it rests on the observations and experimental work of many able men. Sambon's suggestion of the possible sporozoal nature of the disease rests largely on an argument from analogy and is, at present, little more than a suggestion. It offers new and possibly profitable fields of investigation.

The Relation of the Production and Utilization of Maize to Pellagra.—CARL L. ALSBERG of the Bureau of Plant Pathology, Department of Agriculture, Washington, D. C., attributed the increasing prevalence of pellagra in the United States to (1) differences in the variety of corn

grown, (2) changes in the climate, (3) the spreading of the cornbelt northward, (4) the manner of transporting corn, and (5) changes in the methods of milling. In the South the germ of the corn was left in when it was milled, and, for this reason, the meal milled in the South contained a much higher percentage of toxins. He then proposed that the standardization of grain should be carried out by the Federal Government, which should enforce the proper drying of corn.

Dr. George Dock opened the discussion, and said that from Dr. Alsberg's remarks one might get the idea that pellagra had developed in this country simply through the change of conditions for the raising and selling of corn; but Dr. Dock was certain that he had heard of cases before the existence of these changed conditions. He thought that the main point was that it existed now, in a form difficult to recognize, and very often mistaken; as the clinical recognition of the disease was difficult in the less marked cases.

Dr. J. M. Anders called attention to the fact that of 196 cases of pellagra collected by Dr. Wood, 70 occurred in North Carolina. He said that the acute form of pellagra proved fatal in from four to five weeks to three months, this form being unknown in Italy. The average duration of cases here, in the chronic form, was only three years; whereas in Europe it was at least five years.

Dr. Edward Stitt of Washington said that in not a single case of pellagra that had been shown him in Egypt could he see any typical symptoms.

Dr. William Thayer referred to a case that he had seen in 1905. The patient had had two previous attacks, associated with diarrhea, an eruption on the back of the wrists, and marked stomatitis. This condition lasted about a month, and then cleared up. He also said that intensive arsenical treatment had produced some very good results in trypanosomiasis. Therefore it was tried in pellagra on two successive days. In many cases there was a prompt recovery, and it was unnecessary to give the treatment a week later. He considered this result so remarkable that he could not help feeling skeptical regarding it.

Dr. T. B. Futcher of Baltimore asked whether it was known how long a person must be subjected to the infection in order to develop the disease.

Dr. Alsberg said that he did not think there were any exact data regarding this point. He thought that a good many cases were overlooked in this country, especially in colored persons.

Dr. Lavinder said that not enough reports had been received from men who had seen the disease clinically to enable one to draw conclusions. He remarked that, while the Italians do have an acute pellagra, what they mean by this term is an acute exacerbation of a chronic case.

The Method of Teaching Tropical Medicine.—Dr. Edward R. Stitt of Washington referred entirely to the teaching conducted in schools outside of the tropics, in which no tropical material was available. He suggested that, instead of showing a tropical-climate case and giving the differential diagnosis from a temperate-zone disease, one should exhibit a case with a disease common here and differentiate it from one common in the tropics. More attention should also be given to epidemiology; and to relate an amusing anecdote in connection with the description of a disease would often impress students as nothing else could.

A Method for the Preparation of Flat Worms for Study.—Dr. A. J. Mink of Washington gave a concise description of the method.

Dermatobia Noxialis Infection: Report of a Case Contracted in Southern Mexico.—By J. D. Mangee of Atlanta, Ga. (Will be published later.)

Blood-Pressure in Yellow Fever.—Dr. J. Birney Guthrie of New Orleans said in this paper that, after a prolonged study of blood-pressure in the Emergency Hospital in New Orleans, he had come to the conclusion that a low average of pressure was a favorable sign of no little prognostic value, and that a crossing or touching of the curves of blood-pressure and pulse was of great significance. A single observation of blood-pressure was of no value; but the record from day to day was vastly instructive in yellow fever.

Dr. Bass of New Orleans said he felt certain that the general observation of a decline of blood-pressure was the rule. The association of nephritis with the increase of blood-pressure was also confirmed in two cases, one patient dying with absolute suppression of urine and the other with nephritis and black vomit.

A Note on the Ipecac Treatment of Amebic Dysentery.—Dr. George Dock of New Orleans urged the more frequent use of ipecac, the neglect of this being in direct opposition to the strong recommendations made by experienced physicians in India, the United States, and Manila. Vomiting was hardly ever produced, even with doses of 60 or 80 grains a day. The clinical result was most striking; the amebas disappeared quickly, as a rule. Subjective discomfort was often surprisingly slight.

Dr. Stitt said that in the Philippines most excellent results were obtained by the use of ipecac. He also said that he had had an amebic affection for two or three years, and that the only thing that would do him any good was ipecac. After using it for three or four days, however, he would lose his appetite and be forced to discontinue the drug.

Dr. J. M. Anders asked whether Dr. Dock had met with any cured cases, he having found the cure only temporary.

Dr. P. M. Ashburn said that he had never seen any patients who did not promptly recover under ipecac treatment, save one, if they could retain the drug. If he could not cure it within a month he felt doubtful of ever curing it.

Dr. Dock, in closing, said, in answer to Dr. Anders' question, that he had been unable to follow all of his cases up. He considered ipecac more effective in acute cases than any other drug, and had had better results from it in cases of long standing.

Officers.—The following officers were elected for 1909-1910: *President*, Dr. William C. Gorgas, U. S. A.; *Vice-Presidents*, Dr. William S. Thayer of Baltimore and Dr. Rudolph Matas of New Orleans; *Treasurer*, Dr. Charles Lincoln Furbush of Philadelphia; *Secretary*, Dr. John M. Swan of Philadelphia; *Assistant Secretary*, Dr. Edward R. Stitt, U. S. N.; *Councillors* (to serve two years), Drs. Ramon Guiteras of New York and James Ewing of New York. Drs. William S. Thayer of Baltimore and James M. Anders of Philadelphia were elected delegates to the International Society of Tropical Medicine.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held April 1, 1909

The President, Dr. John A. Wyeth, in the Chair.

This meeting was held under the auspices of the Section on Dermatology.

Tuberculosis and Tuberculides of the Skin.—Dr. A. R. Robinson said that the term tuberculosis of the skin had been up to the present time applied to those lesions in which tubercle bacilli had been found *in loco* and regarded as the cause of the tissue changes. The presence of tubercle bacilli was not positive unless it could be shown that they were not a secondary invasion. They might be present, but on account of the limited number, uncolorable condition, or absence in the tissue examined, they might

not be observed. Miliary tubercle structure, when present, was positive, but such structure was not the only kind entitled to be called tuberculosis. Animal inoculations, if positive, were conclusive, but they were often negative in tuberculous cases, as the part used in the experiment might be free of organisms. A marked local reaction after a tuberculin injection was fairly conclusive. Dr. Robinson maintained that whatever tissue changes were caused by tuberculin or by the tubercle bacilli, active, attenuated or dead, having an origin either at the seat of the lesion, or carried to it from a distant part, represented a true tuberculosis, whatever the tissue changes were. There were several clinical forms of tuberculosis among the lesions in which the bacilli were easily demonstrated, and clinicians had made out several varieties of a single form as in lupus vulgaris. That there could be very similar objective forms of disease manifestations of the skin with a very different pathogenesis was well known, otherwise the diagnosis would not be so difficult as it sometimes was among experts, and for a practical illustration of this he referred to the reports of meetings of dermatological societies where cases were shown and discussed. That a definite agent could produce polymorphous eruptions a reference to syphilis alone was sufficient proof. Therefore, the fact that lesions upon the skin had a morphology and a clinical course different from some other lesion was no proof of a different pathogenesis. There was no difference in virulence in the tubercle bacilli of the skin from those of other organs. The character of the lesions in a given case depended, no doubt, on the virulent character and number of bacilli, the mode of infection, anatomical structure and nature of the ground. It was not known, except in this general way, why different forms arose in different persons from the same method of infection. The lesions arose from inoculation, either exogenous or as autoinfection, from contiguity, or were hematogenous, that was through the blood circulation. The term tuberculide had been used since 1896 for certain lesions that could be described as chronic, indolent, necrotic granulomata, with a tendency to softening and death, leaving superficial or deeper scars. They were met with very frequently in association with flagrant chronic tuberculosis, especially of the bones, glands, and skin. They were supposed to differ from the so-called true tuberculosis already referred to by absence of tubercle bacilli, negative animal inoculation, and absence of tubercle structure. They often showed local reaction after tuberculin injection and also positive reaction after tuberculin inoculation. No single one of the above would serve to separate these lesions from the "tuberculoses." He said he had already given his definition of a tuberculosis, and whether these tuberculides were such or not must be decided on that basis. He stated that, although Darier was the first to use the term tuberculide for this group, Dr. Piffard was the first to use the term in 1892 for tuberculous affections of the skin, and to him belonged the priority and credit. What constituted tubercle structure? What tissue changes could be produced by tubercle bacilli in any condition of existence or by diffusible toxin from the bacillus? Professor Orth agreed with the position Dr. Robinson had taken that true tuberculous tissue could exist without the presence of caseation, giant cells, epithelioid cells and lymphoid cells arranged in the classical manner as described in the formation of miliary tuberculosis. Zieler, using pure tuberculin for skin inoculation, found in an early stage nodules along the blood vessels, with round cell infiltration and perhaps slight necrosis, and, at a later stage, extended deeper along the vessels to the deep fascia, while at the place of infection there were epithelioid cells in the blood vessel wall and giant cells in the scar. Tuberculin containing fragments of bacilli did not cause different tissue changes, hence the changes at a distance from the place of infection were the result of a diffusible toxin. Whether a tuberculide was formative or exudative probably depended on the virulence of the virus, number and character of the bacilli and nature of the ground. Necrosis was caused by the toxins. Dead tubercle bacilli could cause granulation tissue formation, but not caseation, nor could they produce a diffusible toxin. According to this observer, it required for skin inoculation only that dissolved chemical substances arising from the bacilli he used, and corpuscular elements could be excluded. He showed that tubercle structure could be produced without bacilli or its fragments or dissolved body substance, that was, that a toxic tubercle structure could exist without an endotoxin. This view was opposed to that of Wolff-Eisner and others, who maintained that the action of tuberculin depended upon what was contained in the bacterium body, and that giant cells were formed where there was a slow bacteriolysis, with freeing of poisonous substances in the bacterium body, that tuberculin reaction depended upon the splitting up of the bacilli, hence the tuberculous structures forming after a von Pirquet inoculation depended on the visible or invisible bacilli fragments that got into the skin and were there dissolved; also that the endotoxin to which the changes were ascribed arose only in the body under the influence of a bacteriolytic substance set free and wrought into action. According to Zieler, the histological changes depended on the action of living bacilli and also from soluble substances and conditions of the tubercle substances.

As regards the etiology of the tuberculides, three views existed—a toxic hypothesis, that was, that the lesions depended upon a toxin carried to the part from a distant tuberculous area; a bacterium hypothesis, that the lesions depended on attenuated or dead bacilli *in loco* or carried to the part as such from a distant part; a third view that there was only an association and not an etiological relation between the tuberculides and tubercle bacilli. For the toxin hypothesis the clinical history, inability to find bacilli, negative animal inoculation and anatomical structure had been urged, but he stated why the search for bacilli was usually in vain and animal inoculation generally negative. Also, the old test for tuberculous structure was not correct, as shown by Orth, Zieler and others. The objection to the bacterium hypothesis was again the absence of bacilli and of tubercle tissue according to the old test, negative animal inoculation and inconstancy of reaction after tuberculin. They might, moreover, have bacilli and animal inoculations fail, and they might have positive inoculations and be unable to find bacilli as in lichen scrofulosorum. In fact, in lupus vulgaris, an admitted tuberculosis, it was very difficult to find bacilli, and this clinical form had never been reproduced by inoculation. Fadasohn believed the lesions arose from material from weak or dead bacilli from a distant part becoming weak or dead at the primary seat or in transit through the blood vessels or at the seat of the cutaneous lesion. The third view that the lesions were not tuberculous but the result of local infection or autoinfection of different agents on a suitable ground as pityriasis versicolor in tuberculous persons, pyodermias in diabetics and scrofulous individuals, and undoubtedly some of the so-called tuberculides had this origin, that was, the diagnosis was not as yet sharply defined. He doubted, however, if that was ever the origin of a chronic necrotic granuloma with caseation. The researches of Gougerot and Laroche, as published in the archives of experimental medicine and pathological anatomy in 1908, seemed to throw much light on the whole subject. They were able to produce the disease (tuberculides) in guinea pigs, with the same clinical, anatomical, and bacteriological characters as were found in the human subject. They made inoculations by scarification, by rubbing into the skin after epilation, and by injection into the

epidermis. Tuberculides with a typical histology were produced by inoculation, by rubbing into the skin, of virulent bacilli. The lesions were almost invariably those of the papulonecrotic form. Well developed lesions formed in about eight weeks. Sometimes typical miliary tubercle structure formed deeper in the tissues, and superficially the structure was atypical, as in human tuberculides. The process could commence as a general epidermis necrosis or with a spongy condition first and later a necrosis. Inoculations into guinea pigs from these lesions were usually negative. They concluded that active bacilli must be used, that the lesions did not depend upon attenuated or dead bacilli if the guinea pig was nontuberculous. Inoculations with attenuated or dead bacilli or with tuberculin in tuberculous animals caused the same lesions, hence tuberculides in the human subject when not caused by direct inoculation of active bacilli must have a hematogenous origin and show that the person has tuberculosis. From all these observations he concluded that all the group of papulonecrotic lesions had a tuberculous basis and, following Piffani, would employ the term tuberculide for all the tuberculous affections of the skin.

Tuberculin Injections in the Treatment of Certain Diseases of the Skin.—Dr. A. Schuyler Clark said that tuberculosis of the skin was not very common, and Dr. Lawrason Brown had told him that in 1,600 cases of pulmonary tuberculosis treated at the Adirondack Cottage Sanitarium he had only seen one case in which the skin was affected. Dr. Clark said he had used the bacillus emulsion for his injections, and regularly began with the dose of 1/10,000 m.gr., the injections being given in the less sensitive portions of the back, biweekly, and under the most careful aseptic precautions; this dose was systematically increased in series of tenths over periods varying from six weeks to several months, the largest dose he had worked any patient up to having been one decigram. On only two occasions had any reaction resulted from these injections. After reporting a number of cases, he offered the following conclusions: (1) Tuberculin had some place in their dermatological armamentarium, but its administration was dangerous and unjustifiable. (2) It seemed to have some therapeutic value and indirectly might even be a curative agent in erythema induratum, granuloma necroticum, lichen scrofulosorum, and their clinical variations, classed under the heading of tuberculides, and due to the tubercle bacillus. (3) Lupus erythematosus and the so-called lupus pernio were probably not tuberculous conditions and would not be benefited by injections of tuberculin. (4) In only a few selected cases with considerable erythema and congestion, probably due to the additional effect of the tuberculous toxins, were tuberculin injections of value in lupus vulgaris and its so-called allied true tuberculosis of the skin, due to the presence of the tubercle bacillus itself, as administered under this safer method. (5) In this latter class of cases, Senger reported cures by inunctions of the Moro tuberculin salve into the lesion itself, producing specific local reaction without constitutional disturbances, and this warranted its trial. (6) In scrofulodermias, and particularly tuberculous ulcerations, even though tubercle bacilli be present, tuberculin injections seemed to be followed by improvement when used along with hygienic and local measures.

The Diagnostic Value of the Inunction Tuberculin Reaction in Cutaneous Tuberculosis.—Dr. William B. Trimble reported the use of the inunction test in fifty-four patients suffering from various diseases of the skin, a number of whom were cases of cutaneous tuberculosis. The test or method was originally devised by Moro of Munich and was supposed to be specific. The positive reaction was divided into three degrees. The first, a mild efflorescence of ten or twelve pin head, dusky red papules, occurring from twenty-four to forty-eight hours after the application of the salve. The other two were exaggerations of the first, with a larger area of erythema surrounding the papules. He had applied the ointment in lupus, both vulgaris and erythematosus, and tuberculosis verrucosa cutis and had used cases of psoriasis and syphilis as controls. In all the cases of skin tuberculosis the reaction was positive. It was also positive in a few cases of psoriasis, some of which were afterward found to be suffering from general tuberculosis, and others in which no focus of tuberculosis could be discovered. In none of the cases of syphilis was there a positive reaction. The reaction was positive in two cases of erythematous lupus and negative in two.

Lantern Slide Exhibition Illustrating the Clinical and Histological Features of the Tuberculoses and the Tuberculides.—Dr. John A. Fordyce showed a number of lantern slides illustrating the early clinical forms of lupus vulgaris of the anterior nares, involving the mucosa and contiguous skin. He stated that statistics showed that in 72 per cent. of all cases of lupus the mucous membranes were involved, and in about 30 per cent. pulmonary tuberculosis was present, the majority of the latter being secondary to the skin affection. In speaking of the clinical manifestations of intranasal lupus, he referred to the frequency with which perforation of the septum occurred. An early case of lupus of the cheek independent of mucous membrane lesions was shown, and the excellent opportunity which these cases offer for Finson light treatment was discussed. Extensive cases with deformity and chronic cases of lupus of the face resulting in scar tissue were also illustrated, as well as multiple lesions involving the face and body and cases of lupus exulcerans, lupus serpigenosus and lupus maculosus. A rapidly spreading tuberculous granuloma of the commissure of the mouth, presenting neither the features of a lupus nor tuberculosis vera, was next shown, and this was followed by slides of tuberculosis verrucosa cutis of the hands about the finger nails and the buttock and of tuberculous dactylitis. Dr. Fordyce then showed illustrations of acnitis and folliclis and stated that, in the opinion of Barthelemy, Crocker, and Schamberg, of Philadelphia, the acnitis of the face, which was called by Tilbury Fox disseminated follicular lupus, was related in no way to that infection. He also showed a case of extensive scarring of the entire body following an infection of some kind of the pilosebaceous apparatus. This case had been carefully observed by Dr. Trimble, and it was difficult to say whether it was related to the papulotuberculides or not. There was, in the opinion of Dr. Fordyce, a papulonecrotic tuberculide often found associated with glandular and other forms of tuberculosis which gave a positive tuberculin reaction. This form was probably embolic in origin and due to the tubercle bacilli. He showed some further slides illustrating erythema induratum and spoke of the distinction made by Whitfield of the two types, one tuberculous and the other possibly rheumatic. Lupus erythematosus, a typical butterfly lesion, and another more unusual one on the side of the face were shown to illustrate the differences between it and the tuberculous diseases. A number of histological slides illustrated the manner in which infection took place in the skin in lupus and the different ways in which the skin reacted to the infection and the development of the tubercle and subsequent necrosis or fibrosis. These were followed by slides of plasma, epithelioid and giant cells, follicular lupus, lupus in scar tissue, and tuberculosis verrucosa cutis. Early and advanced stages demonstrating the histology of erythema induratum, of necrotic tuberculide and of lupus erythematosus concluded the exhibition.

Dr. Milton B. Hartzell of Philadelphia said that he had accepted the invitation to be present and discuss the papers mainly for two reasons. First, the time was opportune for a discussion of such a subject, a time when the
